<b>Annex 1. RCP emissions scenarios and projections consistent with current policies and ambitions.....</b>	<b>28</b>

## Key Messages and outline

This is the introduction to the Technical Report of 3<sup>rd</sup> UK Climate Change Risk Assessment (CCRA3). It sets the context for CCRA3 and provides some key background information.

- With current commitments and ambition on emissions, global warming could reach between approximately 2°C and 4°C by the end of this century, or potentially even higher.
- Even if the international community meets the goals of the Paris Agreement, further climate change will occur and hence will require adaptation.
- This CCRA3 Technical Report assesses the urgency of adapting to UK climate risks and opportunities, considering both the current climate and projected future climates consistent with two future pathways:
  - (i) stabilising 2°C by the end of the century, representing achievement of the Paris Agreement goals;
  - (ii) 4°C global warming at the end of the century the current trajectory, consistent with the current limited global ambition for reducing emissions
- This includes risks and opportunities arising from climate change within the UK and from the impacts of climate change elsewhere in the world.
- 61 risks are assessed, grouped into 5 categories:
  - Natural Environment and Assets
  - Infrastructure
  - Health, Communities and the Built Environment
  - Business and Industry
  - International Dimensions
- The extent to which current UK adaptation plans will manage these risks is also assessed, and the benefits of additional action on adaptation within the next 5 years. The risks are scored according to the urgency of additional adaptation action.

As context, section 1 gives the terms of the CCRA in the Climate Change Act (2008) and Climate Change (Scotland) Act 2009, and its purpose in informing the UK and devolved national adaptation programmes. It explains the aim of providing advice on the relative urgency of new government action on adaptation in different risk areas. The CCRA does not recommend specific actions that should be taken, as that is out of scope. Section 1 also outlines the structure of the CCRA3 process and where the Technical Report is placed within this. This section also summarises how the evidence and context has changed since the 2<sup>nd</sup> UK Climate Change Risk Assessment (CCRA2).

As background specific to CCRA3, section 2 provides the definition of risk used in this assessment. It gives a brief overview of similarities and differences in the approach of CCRA3 compared to CCRA2.

Section 2 also describes how CCRA3 frames the view of future climate change to give a clear and consistent assessment of future risks within the numerous and highly complex set of possible climate futures. This includes the consideration of potential outcomes either with or without further action on mitigation in the context of the Paris Agreement and the UK, Scottish and Welsh targets for reaching Net Zero emissions (hereafter referred to as “Net Zero”). It also introduces key aspects of the socioeconomic context, again including Net Zero, the UK’s exit from the European Union, and also the emergence of potential implications of the Covid-19 pandemic.

Section 3 outlines the sources of evidence for CCRA3, including how existing academic literature and non-academic reports are brought into the process and how these are supplemented by new analysis carried out specifically for CCRA3. The method for considering the new UK Climate Projections alongside evidence based on previous projections is introduced.

Section 4 provides an overview of the technical chapters, giving a brief summary of the scope and listing the specific risks that are examined.

## 1. Context

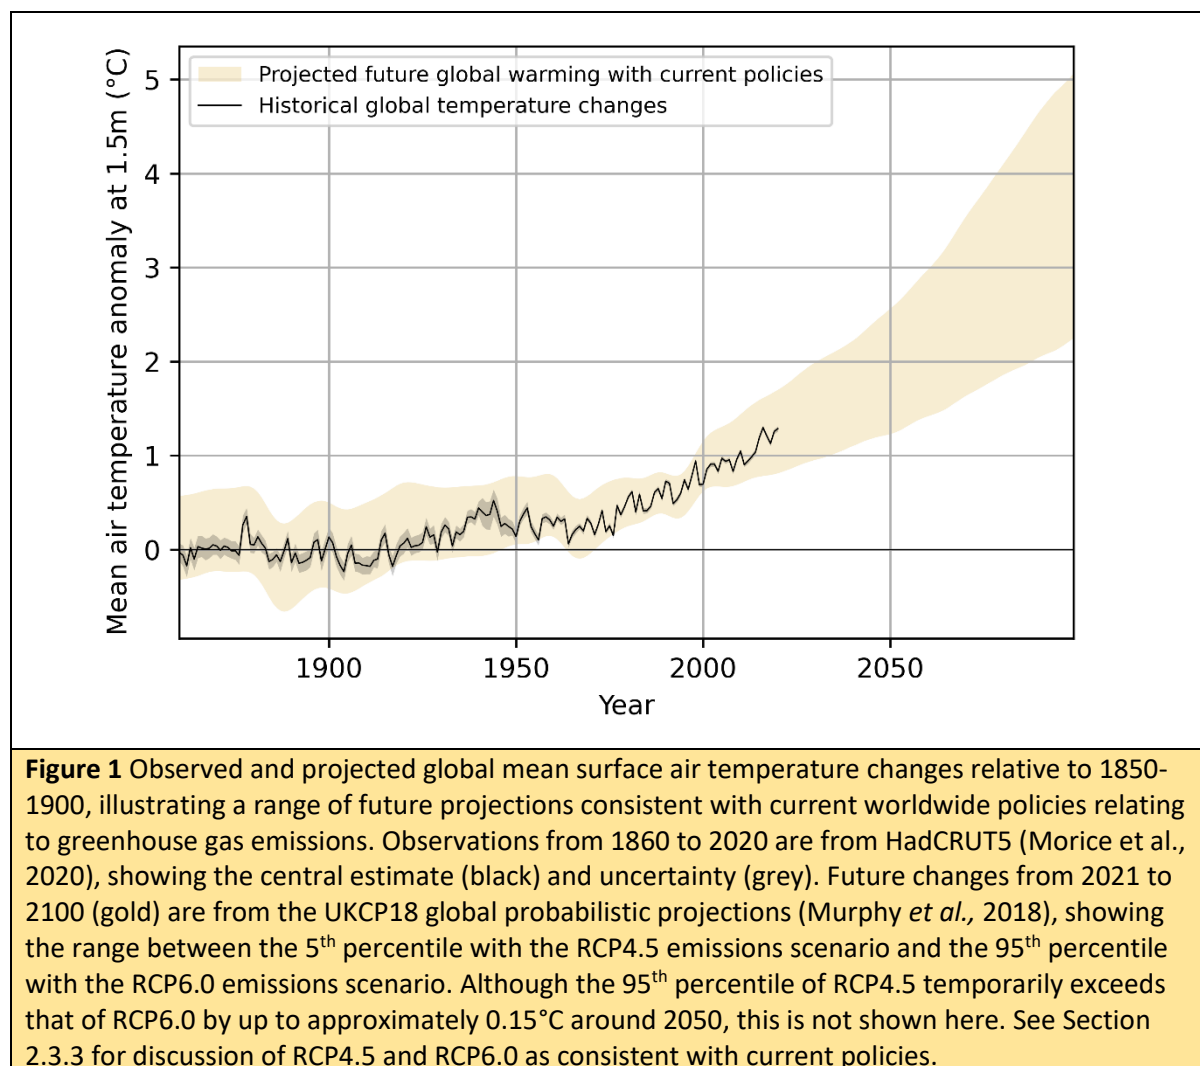

### 1.1 Human-caused climate change and the need for mitigation and adaptation

It is beyond doubt that the global climate is changing due to human alterations of the composition of the atmosphere and the character of the land surface. The global average surface temperature has risen by over 1°C compared to conditions before the industrial revolution (Chapter 1: Slingo, 2020). This is bringing unfamiliar local weather patterns, making some types of extreme weather events more likely, and causing an accelerated rise in sea levels. These changes are altering the stability of ecosystems and habitats, and increasing weather-related risks to people, both around the world and in the United Kingdom.

Although the Paris Agreement commits the nations of the world to limit global warming to well below 2°C above pre-industrial levels and pursue efforts to limit warming to 1.5°C, projections consistent with policies currently in place worldwide imply warming of between approximately 2°C and 5°C by the end of this century (Figure 1) depending on the rate of greenhouse gas emissions and the response of the climate system to these emissions. This will further increase the shifts in weather patterns and extremes, further increasing risks to people and biodiversity, with higher warming leading to greater risks.

Limiting warming to lower levels may still be achievable if global emissions are rapidly reduced to net zero or net negative, but even if global warming is successfully limited to between 1.5 and 2°C, weather patterns will still be different to those in recent decades, and sea levels will continue to rise to some extent. Adaptation to at least this minimum level of change is therefore needed, and also needs to be assessed for larger changes since the actual future level of warming and associated climate hazards cannot be known. Both mitigation and adaptation are therefore required to minimise risks from human-caused climate change.

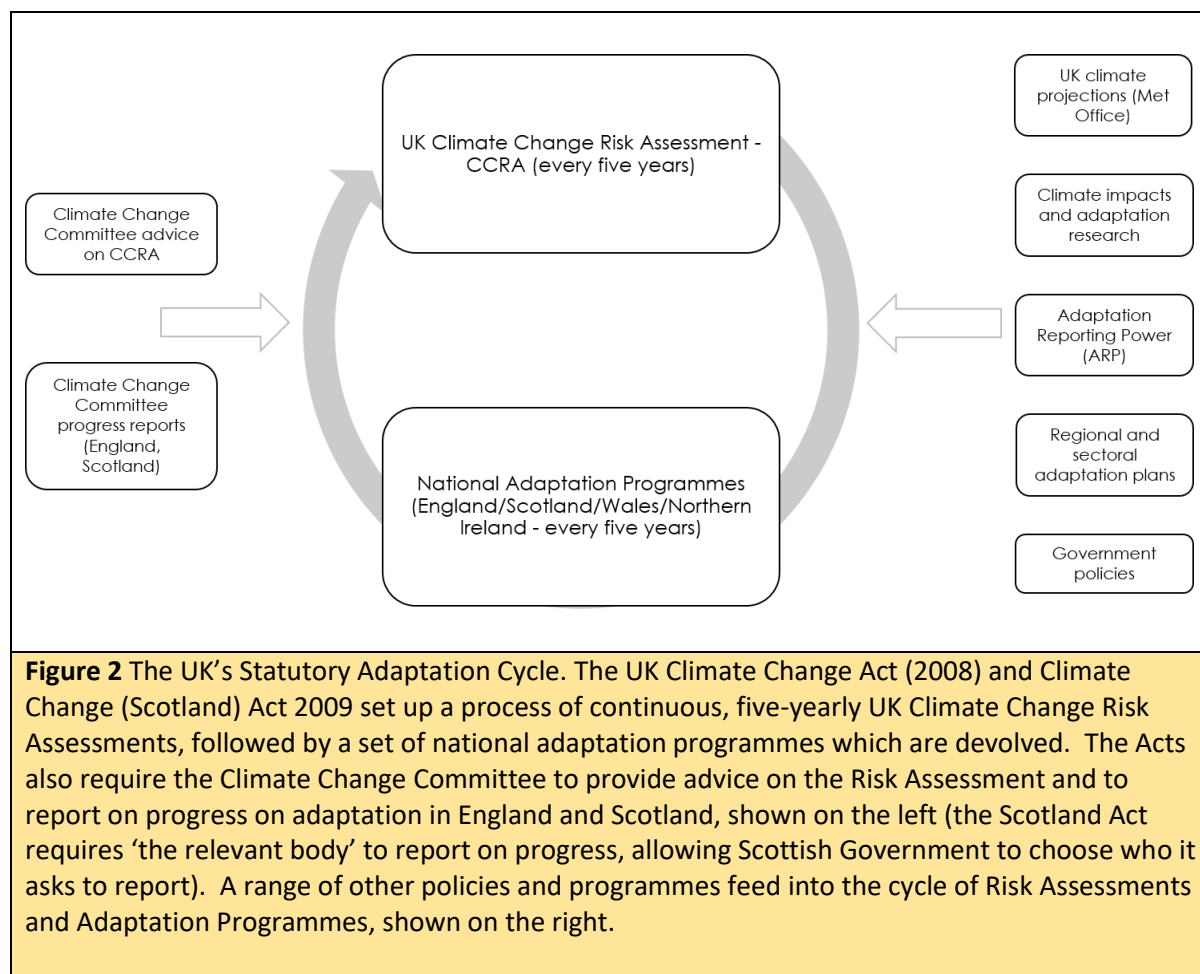

## 1.2 The Climate Change Act and National Adaptation Programme

The UK Climate Change Act (2008) and Climate Change (Scotland) Act 2009 set out a statutory five-yearly cycle of UK climate change risk assessments, followed by national adaptation programmes for England, Northern Ireland, Scotland and Wales. Each cycle leads into the next so that learning, experience and adaptation action can feed through and result in progress in adapting to climate change in the UK over time. Figure 2 shows this cycle.

The Climate Change Act also set up the Climate Change Committee and its Adaptation Committee. The Adaptation Committee has two statutory roles under the UK Act; to provide advice to the UK Government and devolved administrations on climate change risks and opportunities, and to assess progress in adapting to climate change in England. Under the Climate Change (Scotland) Act, it can also assess progress of the Scottish Climate Change Adaptation Programme. This is also shown in Figure 2.

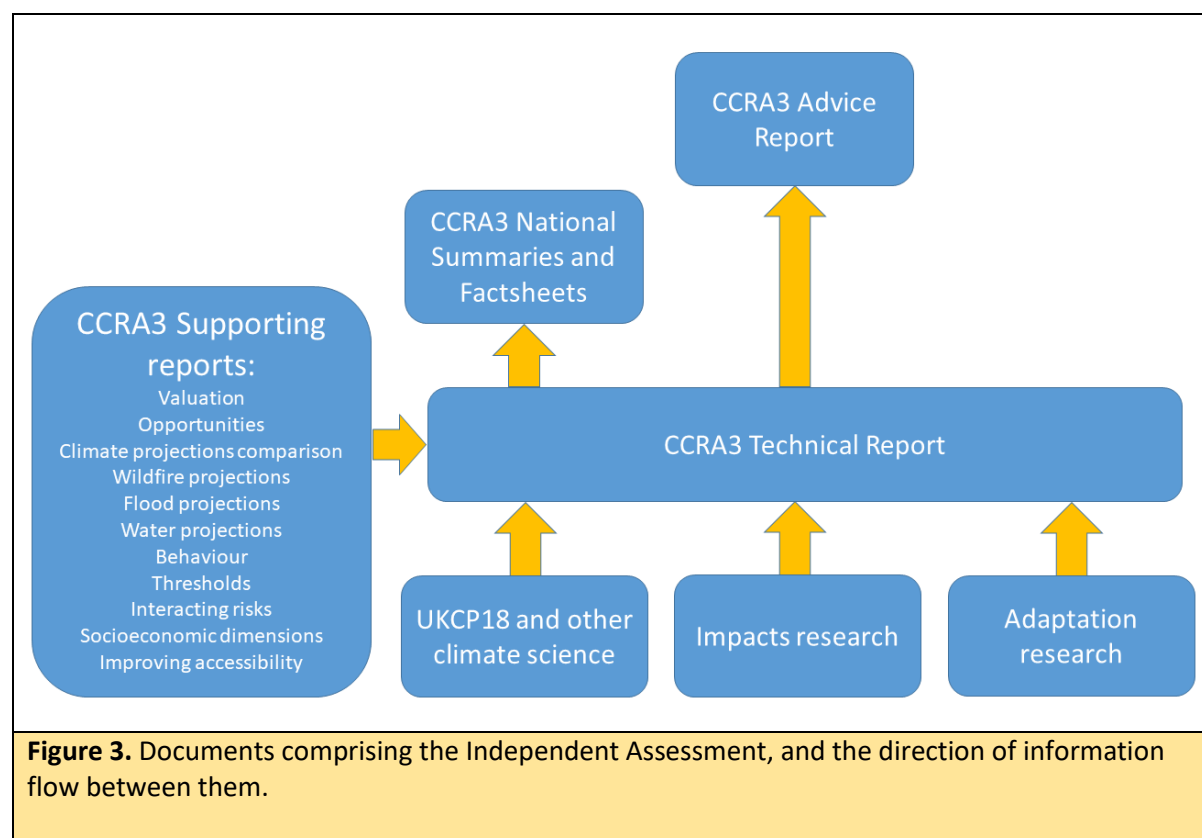

### 1.3 The Climate Change Risk Assessment (CCRA) process and structure

The first CCRA was published by the Department for Environment, Food and Rural Affairs (Defra) in 2012, and the second in 2017. For the third assessment, CCRA3, as it did for CCRA2 in 2016, Defra has asked the Adaptation Committee to prepare an Independent Assessment as a component of its statutory advice on the CCRA (see Figure 2), synthesising the latest evidence on the risks and opportunities to the UK from climate change.

This Technical Report is part of the set of reports that together make up the Independent Assessment to fulfil that request (Figure 3). It collates together the latest evidence and provides urgency scores for each risk or opportunity considered, implementing the method set out in chapter 2. In addition to the Technical Report, the Independent Assessment also consists of a number of supporting research reports, summary documents (by UK country and sector) and an Advice Report that forms the Committee's statutory advice to government. The information flow between these documents is shown in Figure 3, and the purpose of each is shown in Table 1.

**Table 1.** Purpose of documents of the CCRA3 Independent Assessment

Document	Purpose
Advice Report	Summarises and interprets the evidence provided in the technical chapters. Also provides the Adaptation Committee's statutory advice to Government on the risks and opportunities to the UK from climate change. Authored by the CCC.
Technical Report	Provides the detailed analysis that underpins the assessment of risks or opportunities, and the resulting urgency scores. Alongside this introduction, there are seven technical chapters. Evidence is drawn from the literature and new research. Authored by a consortium of experts led by the University of Exeter in partnership with the Met Office, working to the CCC.
Summaries	Two types: National Summaries that summarise the most relevant aspects of the risk assessment for each UK country (England, Northern Ireland, Scotland and Wales), and a set of seventeen factsheets that summarise the risks and opportunities for a range of topics relevant to different government bodies. Authored by a consortium of experts led by Sustainability West Midlands working to the CCC.
Supporting reports	Provides supporting evidence to inform the technical chapters, supplementing the existing literature and filling key evidence gaps from CCRA2 or updating analysis with new information. Authored by consultants working to the CCC and by researchers in other programmes.

The CCRA3 Technical Report was commissioned by the CCC but produced through a large consortium of experts coordinated by the University of Exeter in partnership with the Met Office. Authors are listed at the beginning of each Technical Report chapter.

The governance for the Independent Assessment included a Customer Group (UK Government and devolved administration funders) to provide feedback to the CCC on progress and comment on whether the outputs were fit for purpose and met the aims of the Customer Requirement, which was provided to the CCC in 2018. The Customer Group was supported by a Project Board made up of government departments and agencies from across the UK. The CCC was also supported by an expert advisory panel of independent experts who commented on the priorities and analytical approach of the assessment early on in the process.

The production of the Independent Assessment has undergone an extensive stakeholder engagement and review process. Over 450 people from 130 organisations have been involved in developing the set of reports in the assessment. The Method (Chapter 2: Watkiss and Betts, 2021) was developed by the CCC in consultation with the academic community and other stakeholders. The list of risks assessed was initially developed by the CCC and government stakeholders, and further evolved through collaboration between the Technical Report authors, the CCC and stakeholders. The CCC organised stakeholder meetings for government officials and other interested groups in London, Belfast, Edinburgh, and Cardiff throughout 2019 and into 2020. These meetings focussed on collating available evidence and policy updates. Two drafts of the technical chapters were reviewed by three different review groups; a technical peer review panel; a government review group, and a group of external reviewers who responded to an open call, in order to provide independent comments. In total, over 5,000 review comments were received on the technical chapters and the responses to each comment were collated and are available upon request. The final CCRA3 Technical Report is an independent report based on evidence from the literature and new research, having been scrutinised through the review process. Where expert interpretation has been necessary due to incomplete or conflicting evidence, this represents the views and judgement of the authors of the respective Technical Report chapters and has been identified as such.

The primary intended audience for the Independent Assessment is the departments of the UK Government, departments of the devolved administrations, and their respective Arm's Length Bodies. The Government also asked that the report is written with a secondary audience in mind of organisations making significant policy or investment decisions. These key stakeholders have been involved throughout the process, in particular through the scoping the CCRA3 Technical Report and providing input relating to adaptation issues within their remit. It should be noted however that the individual chapters of the CCRA3 Technical Report are the product of their respective authors only (listed at the front of each chapter). The accompanying Advice Report represents the Climate Change Committee's interpretation of the evidence set out in the Technical Report, including their official advice as required under the UK Climate Change Act (2008).

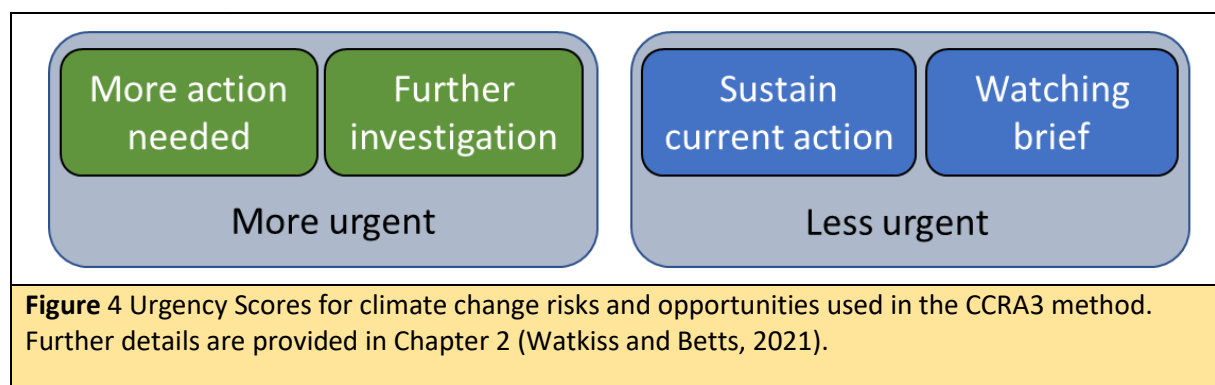

### 1.4 Purpose of the CCRA

The aim of the CCRA3 Independent Assessment is to address the following question, as it was for the previous CCRA:

*“Based on our latest understanding of current, and future, climate risks/opportunities, vulnerability and adaptation, what should the priorities be for the next UK National Adaptation Programme and adaptation programmes of the devolved administrations?”*

As for CCRA2, the analysis set out in this report seeks to characterise each risk or opportunity by scoring the degree of urgency it poses in the next five years – more urgent risks and opportunities being classified as either ‘more action needed’ or ‘further investigation’ (Figure 4). For the former, the Urgency Score implies that additional adaptation is needed urgently, either over and above what is already happening, or in some cases adaptation needs to start in cases where there is currently nothing happening. Further investigation denotes risks or opportunities where not enough evidence is available to make a robust judgement on what further action is needed. Less urgent risks and opportunities are not scored as ‘do nothing’ but rather as either sustaining current action if the amount of action is in line with the magnitude of the risk or opportunity, or as a ‘watching brief’ where further action is not currently justified, but monitoring the situation is.

It is important to note that this report focusses on current and future risks and not the specific adaptation actions that are needed to reduce risk in the future. The report identifies specific areas where further action is felt to be needed, based on the available evidence. It does not take the further step of recommending what specific actions should be taken, though it does discuss the benefits of taking further action, and this by necessity includes commentary on specific actions. The task for the UK Government and devolved administrations, following this assessment, is weighing up the costs and benefits of different options and setting objectives and actions in the next national adaptation programmes.

This CCRA3 Technical Report draws on the new adaptation policies and programmes set out in updated national adaptation programmes published since CCRA2 (Defra (2018), Welsh Government (2019), Scottish Government (2019), Department of Agriculture, Environment and Rural Affairs (Northern Ireland (2019)).

## 1.5 Evolution of the evidence and context since the 2<sup>nd</sup> UK Climate Change Risk Assessment

Scientific evidence for ongoing climate change and the role of human influence has continued to accumulate and further strengthen since CCRA2. This is partly because climate change itself is continuing, and partly because observational datasets and techniques for analysis and modelling continue to improve. Methods for quantifying the influence of climate change on the likelihood and severity of extreme weather events have been developed further and applied more widely (Swain *et al.*, 2020; Herring *et al.*, 2021). The assessment of the potential for unprecedented events even under the current climate is a particular area of substantial progress since CCRA2 (e.g., Thompson *et al.*, 2017). Furthermore, the new generation of climate models, with updated representations of scientific understanding and higher spatial and temporal resolution, has improved skill in simulating some regional climate processes, and these form a key part of the new UK Climate Projections (Lowe *et al.*, 2018). Analysis and understanding of socioeconomic components of climate risk has also evolved, and more integrated approaches to risk assessment are becoming more widely employed. A number of national climate risk assessments have been published in various countries, as described in Chapter 2 (Watkiss and Betts, 2021), with new approaches to the communication of climate risk being developed and implemented (Sustainability West Midlands, 2020).

The political and societal context has also evolved significantly since CCRA2 was published in 2017. Following the publication of the IPCC Special Report on Global Warming at 1.5°C (IPCC, 2018), numerous countries are preparing more ambitious climate mitigation commitments than previously adopted following the publication of the IPCC Special Report on Global Warming at 1.5°C. This includes the UK's ambition and statutory target to achieve Net Zero greenhouse gas emissions by 2050, with separate accompanying targets for Net Zero by 2045 in Scotland, 2050 in Wales, and a target still to be confirmed for Northern Ireland. Worldwide this is a rapidly-changing situation, with new announcements of country targets being made in advance of COP26. Alongside this, public concern over climate change has become much more prominent, with growing calls for stronger action accompanied by campaigns taking various forms including pressure group activity, school strikes and civil disobedience. Citizens Assembly approaches are being implemented as a means of facilitating and publicising structured public discussion on climate change, with the Climate Assembly UK being one example (Climate Assembly UK, 2020).

Other potentially important changes in the socioeconomic context include the UK's exit from the European Union, and the shifts this will create in environmental policy, trade, and potentially, cooperation on issues such as monitoring and shared research programmes.

Moreover, and significantly, the world has been dealing with the effects of the SARS-Cov-2 (Covid) pandemic, which at the time of writing remains severe and ongoing. The long-term effects of the pandemic are difficult to predict, and there are potentially profound effects on human vulnerability to climate change through increasing inequality, reduced resources and capacity to cope with other shocks. The experience of the pandemic could also lead to a change in how governments view and plan for risk, but it remains too early to tell at the time of writing.

## 2. The CCRA3 approach to assessing climate change risks and opportunities for the UK

### 2.1 Definition of risk and opportunity

This Report uses the same definition of risk as was presented in the CCRA2 Evidence Report; ‘the potential for consequences where something of value is at stake and where the outcome is uncertain’. When used in its general sense, the word ‘risk’ is taken to include both negative and positive consequences, and so includes opportunities. However, the CCRA3 method differentiates between *assessing* negative risks and positive opportunities, and these are reported separately throughout the technical chapters and in the synthesis report as far as possible. The risk descriptors (see Section 4 below) are marked up as risks, opportunities, or both in some cases where there are a range of effects on a given receptor.

Risk assessments often use measures of probability and consequence to characterise the risk, and attempts are made to define these quantities as accurately as possible. Some risk assessments consider the potential for a specific event to happen, as is done in the UK National Risk Assessment which is led by the Cabinet Office. Other studies, particularly climate change risk assessments often look at the potential change (e.g., mean or variability) in a variable such as temperature or rainfall.

In all cases, climate change risk assessments must cope with a large amount of uncertainty. Although all of the risks discussed in this report have some implicit likelihood associated with them, it cannot be quantified precisely. In some cases, we have collected information on probabilities attributed to changes in variables or events, based on an understanding of how the physics of the climate system may change in the future. Climate simulations such as those presented in the 2018 UK Climate Projections (UKCP18: Lowe *et al.*, 2018) and other sets of projections give a current best estimate of which changes in the UK and global climate are more or less likely than others for any given emissions scenario, but these probabilities do not include all sources of uncertainty, and only represent changes in the climate such as temperature and sea level, rather than impacts such as flooding. Rather than provide an estimate of likelihood for individual risks, the authors estimate the magnitude of the impact specified in the name of the risk descriptor, for specific time periods in specific climate futures - the 2050s and 2080s on pathways to approximately 4°C and 2°C global warming in the late 21<sup>st</sup> Century. These are considered to broadly represent lower and upper rates of climate change consistent with either current policies relating to greenhouse gas emissions or the successful achievement of international climate policy ambitions - the rationale for each is described in Section 2.3 below. The definition of magnitude is outlined in Chapter 2 (Watkiss and Betts, 2021).

As well as estimating the magnitude of specific impacts within the range of 2°C to 4°C global warming late this century, the assessment also considers low likelihood, high impact events that sit outside of the assessment of magnitude. The approach to this is described below and set out in more detail in Chapter 2.

As a risk assessment, the focus of CCRA3 is not necessarily on the most likely outcomes, but on outcomes that are likely enough to warrant consideration. The judgement of this depends on the

magnitude of the potential impact – an event which would have extremely severe consequences may warrant consideration in the risk assessment even if it has a very low likelihood of occurring.

## 2.2 Risks and opportunities considered in CCRA3

CCRA3 assesses a set of 61 specific risks and opportunities to the UK from climate change (Table 2). As was the case for CCRA2, the list of risks and opportunities (Table 2) was decided on through an extensive process of consultation between the Government Customer, the CCC and the authors of the technical chapters. Taking the list from CCRA2 as a starting point, the CCRA Customer Group and Project Board suggested various modifications to make the list more policy relevant. The list was refined over a 9 month period with input from the CCC's Adaptation Committee and the chapter authors, and was refined further after the first order draft chapters were produced to limit duplication of analysis across different risks and to fill a few gaps identified by the authors. The focus of the list is to create a set of risks and opportunities that have direct relevance to different government bodies.

**Table 2** Risks and opportunities assessed in the CCRA3 Technical Report

	<b>Natural Environment and Assets</b>
N1	Risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion).
N2	Risks to terrestrial species and habitats from pests, pathogens and invasive species
N3	Opportunities from new species colonisations in terrestrial habitats
N4	Risk to soils from changing climatic conditions, including seasonal aridity and wetness.
N5	Risks and opportunities for natural carbon stores, carbon sequestration from changing climatic conditions, including temperature change and water scarcity
N6	Risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind and saline intrusion).
N7	Risks to agriculture from pests, pathogens and invasive species
N8	Risks to forestry from pests, pathogens and invasive species
N9	Opportunities for agricultural and forestry productivity from new/alternative species becoming suitable.
N10	Risks to aquifers and agricultural land from sea level rise, saltwater intrusion
N11	Risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts.
N12	Risks to freshwater species and habitats from pests, pathogens and invasive species
N13	Opportunities to freshwater species and habitats from new species colonisations
N14	Risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures.
N15	Opportunities to marine species, habitats and fisheries from changing climatic conditions
N16	Risks to marine species and habitats from pests, pathogens and invasive species
N17	Risks and opportunities to coastal species and habitats due to coastal flooding, erosion and climate factors.
N18	Risks and opportunities from climate change to landscape character
	<b>Infrastructure</b>
I1	Risks to infrastructure networks (water, energy, transport, ICT) from cascading failures

I2	Risks to infrastructure services from river, surface water and groundwater flooding
I3	Risks to infrastructure services from coastal flooding and erosion
I4	Risks to bridges and pipelines from flooding and erosion
I5	Risks to transport networks from slope and embankment failure
I6	Risks to hydroelectric generation from low or high river flows
I7	Risks to subterranean and surface infrastructure from subsidence
I8	Risks to public water supplies from reduced water availability
I9	Risks to energy generation from reduced water availability
I10	Risks to energy from high and low temperatures, high winds, lightning
I11	Risks to offshore infrastructure from storms and high waves
I12	Risks to transport from high and low temperatures, high winds, lightning
I13	Risks to digital from high and low temperatures, high winds, lightning
<b>Health, Communities and the Built Environment</b>	
H1	Risks to health and wellbeing from high temperatures
H2	Opportunities for health and wellbeing from higher temperatures
H3	Risks to people, communities and buildings from flooding
H4	Risks to the viability of coastal communities from sea level rise
H5	Risks to building fabric
H6	Risks and opportunities from summer and winter household energy demand
H7	Risks to health and wellbeing from changes in air quality
H8	Risks to health from vector-borne disease
H9	Risks to food safety and food security
H10	Risks to water quality and household water supplies
H11	Risks to cultural heritage
H12	Risks to health and social care delivery
H13	Risks to education and prison services
<b>Business and industry</b>	
B1	Risks to businesses from flooding
B2	Risks to businesses and infrastructure from coastal change from erosion, flooding and extreme weather events
B3	Risks to business from water scarcity
B4	Risks to finance, investment and insurance including access to capital for businesses
B5	Risks to business from reduced employee productivity due to infrastructure disruption and higher temperatures in working environments
B6	Risks to business from disruption to supply chains and distribution networks
B7	Opportunities for business from changes in demand for goods and services
<b>International Dimensions</b>	
ID1	Risks to UK food availability, safety, and quality from climate change overseas
ID2	Opportunities for UK food availability and exports from climate impacts overseas
ID3	Risks and opportunities to the UK from climate-related international human mobility
ID4	Risks to the UK from international violent conflict resulting from climate change overseas
ID5	Risks to international law and governance from climate change that will impact the UK
ID6	Opportunities from climate change (including Arctic ice melt) on international trade routes
ID7	Risks associated with international trade routes
ID8	Risk to the UK finance sector from climate change overseas
ID9	Risk to UK public health from climate change overseas
ID10	Systemic risk arising from the amplification of named risks cascading across sectors and borders

## 2.3 CCRA3 Urgency Scoring approach compared to CCRA2

The CCRA3 Technical Report assesses the urgency of adaptation to the risks and opportunities in Table 2 with a 3-step Urgency Scoring approach (Figure 5). This follows a broadly similar approach to CCRA2.

Step 1 assesses the current and future magnitude of risk, and step 2 assesses the extent to which the risk will be addressed by current adaptation or adaptation already planned. Step 3 assesses the benefits of additional action within the next 5 years. The approach has been further developed to bring in further information within these steps, such as the potential for lock-in of inappropriate or maladaptive responses, the potential to exceed critical thresholds that impact on the effectiveness of adaptation, and interactions between individual risks. For each risk, these 3 main steps and additional sub-steps determine the urgency score (Figure 5).

For risks and opportunities within the UK, the risk magnitude and adequacy of current adaptation were assessed for each of the 4 UK nations wherever possible. Where there was not sufficient evidence to distinguish between the nations, the same risk magnitude and adaptation scores were assigned to all. The overall urgency score was provided for all nations. International risks and opportunities were assessed at the level of the UK as a whole.

As with CCRA2, much of the evidence for the risk assessment is drawn from the existing literature. However, more substantive bespoke research has been possible in CCRA3 compared to CCRA2, enabling some key knowledge gaps to be addressed, including socioeconomic scenarios, interacting risks, thresholds in the natural environment, and human behaviour (see Chapter 2, Watkiss and Betts 2021, section 2.2.4).

A further difference in approach is necessitated by the publication of new climate projections, UKCP18. Although the assessment of several risks benefitted from new analysis using UKCP18, much of the existing evidence on future UK risks is based on earlier projections such as UKCP09, so the approach needed to take account of this. This is described further in Section 3.3 below, and in Chapter 2.

## 2.4 Framing the current and future climate context for CCRA3

### 2.4.1 Overview

Assessing the urgency of adaptation requires information on climate and weather conditions that could occur under current and future conditions.

Assessment of the current risk magnitude take account of current weather and climate hazards and the exposure and vulnerability of people and the natural environment to these hazards. The overall risk may already have been present in a climate unperturbed by human influence, or may have increased in recent years due to changes in climate, socioeconomic factors, or non-climatic human influence on the environment (such as land use affecting habitats).

For the current climate, observed weather data clearly provides a major source of evidence for trends in average climate conditions, the magnitude of extreme weather conditions that can already occur, and whether these extremes are changing. Observed trends in data relating to ecosystems or people potentially provide evidence for whether impacts are occurring, and impacts of past extreme weather events also provide data on the magnitude of current risks. Event attribution techniques can be used to assess the change in likelihood of extreme weather events, not only for changes in temperature extremes but also now for extreme precipitation (Swain *et al.*, 2020; Herring *et al.*, 2021).

However, observed data may not capture the full range of possibilities or give a true picture of the likelihood of particular events, even under the current climate. By definition, extreme events are rare and hence may not have yet occurred in particular locations, even if they are possible. Similarly, some events may have occurred occasionally, but are actually more likely than would be expected from past statistics. Recent advances in climate science have made it possible to assess the likelihood of rare or unprecedented events (Chapter 1: Slingo, 2021). This new capability, along with analysis of observed trends and event attribution, can in principle be used to inform an assessment of the current magnitude of risks, which may now be higher than that assumed purely on the basis of past experience.

For future climate, a very wide range of conditions are possible, depending on natural climate variability, the extent of human influence, and the response of the climate system to this influence. Future climate projections are often framed in terms of climate system responses to specific

scenarios of emissions or specific rates of build-up greenhouse gases in the atmosphere. However, CCRA3 takes a different approach. Since the focus of the CCRA is on informing adaptation, the assessment is framed in terms of risks associated with particular future pathways of future climate change which could come about through different combinations of circumstances, rather than focussing on the details of how these pathways may come about.

Specifically, the framing for future climate this century is in terms of two main outcomes for detailed analysis, plus a third set of outcomes providing wider context for the risk assessment:

- (i) An approximate minimum level of global warming that can be expected if humans take action to reduce their influence on climate. This provides information on the minimum level of change for which further adaptation will be necessary.
- (ii) An approximate maximum rate of global warming consistent with a continuation of current human influence, accounting for uncertainties in anthropogenic greenhouse gas emissions and the climate system response. This quantifies the risks that we wish to avoid or reduce through mitigation, or for which adaptation may be needed if no mitigation action occurs. A maximum rate of warming is considered, rather than a central estimate, since this is a risk assessment rather than a prediction of “most likely” futures
- (iii) Higher rates of warming above those currently considered consistent with the current trajectory, and low-likelihood, high-impact events such as climate system tipping points. Again, this is necessary in a risk assessment since the future cannot be predicted with high confidence.

The first outcome is represented by a pathway in which warming is limited to approximately 1.5°C to 2.5°C global warming, and the second by a pathway in which warming reaches approximately 4°C global warming between 2080 and 2100 (Figure 6). Both of these are used for detailed analysis in the assessment, and the rationale for each is described below. The use of approximate rather than precise definitions of global warming levels allows a number of relevant projections to be included in the evidence base for each, including the 5<sup>th</sup> Coupled Model Intercomparison Project (CMIP5) models and the previous set of UK projections, UKCP09, amongst others, some using RCP scenarios and others using different scenarios<sup>1</sup>. Further details of the sets of projections and scenarios aligned to both the 2°C and 4°C warming pathways are provided in Chapter 2 (Watkiss and Betts, 2021).

The third group of outcomes recognises the possibility of even higher rates of warming, as part of a wider approach of considering low-likelihood, high-impact outcomes to allow for informed decision-making in cases when such outcomes may be important. Such a very high scenario is distinct from the scenario of approximately 4°C global warming at the end of century. The rationale for the distinction between these scenarios and the upper bound of the higher ‘main analysis’ scenario is provided below.

Information on low-likelihood, high-impact events is also considered. Some of these, such as tipping points or strong feedbacks involving the carbon cycle, may themselves lead to faster rates of warming or sea level rise. Others may change the climate outcome to one of an entirely different

---

<sup>1</sup> The new CMIP6 climate models are driven by the Shared Socioeconomic Pathway (SSP) scenarios rather than the RCPs. However, since the CCRA3 assessment is framed in terms of pathways to global warming levels rather than emissions scenarios, the use of the RCPs does not affect the relevance or timeliness of the analysis.

nature to that in the main projections. These are not used directly for assessing the magnitude of risks or for scoring the urgency of adaptation, but are presented as wider context so that they can be considered if any adaptation decisions are very sensitive to low-likelihood, high-impact outcomes.

#### 2.4.2 Lower pathway: approximately 2°C global warming in the late 21<sup>st</sup> Century

The lower scenario represents an approximate minimum level of future climate change to which adaptation will be necessary, defined as a stabilisation of global warming at 2°C above 1850-1900 levels by 2100 with a tolerance of  $\pm 0.5^\circ\text{C}$  (Figure 6). This therefore includes outcomes which meet the aims of the Paris Agreement by limiting warming to between 1.5°C and 2°C, and also allows for consideration of studies with “temperature overshoot” scenarios reaching up to 2.5°C warming. This range encompasses a large proportion of the UKCP18 global probabilistic projections with the RCP2.6 emissions scenario and CMIP5 projections with the RCP2.6 concentration pathway.<sup>2</sup>

<sup>2</sup> The RCPs (Representative Concentration Pathways) are used in two ways: (i) emissions scenarios, when Earth System Models calculate the change in CO<sub>2</sub> concentrations, accounting for climate-carbon cycle feedbacks, as

This broad definition with a tolerance of  $\pm 0.5^{\circ}\text{C}$  should not be taken to imply that the difference between  $1.5^{\circ}\text{C}$  and  $2^{\circ}\text{C}$  global warming is considered negligible. The IPCC (2018) clearly demonstrated that at the global scale, projected global impacts are generally larger at  $2^{\circ}\text{C}$  warming compared to  $1.5^{\circ}\text{C}$ . It is simply that a greater level of precision is not justified in the context of the 4 broad categories of urgency score used to frame the outputs of the CCRA3 Technical Report (Figure 4). Since climate change uncertainties are more substantial at smaller scales (see Chapter 1: Slingo, 2021), many of the possible UK-scale risks associated with over  $2^{\circ}\text{C}$  global warming could also apply at  $1.5^{\circ}\text{C}$  warming. Hence, a wide definition of the scenario ensures that all studies with relevant information for a minimum level of UK climate risk can be considered.

#### 2.4.3 Higher scenario: approximately $4^{\circ}\text{C}$ global warming at the end of the 21<sup>st</sup> Century

The higher scenario represents a rate of global warming that could occur if action to mitigate climate change fails to go beyond current pledges. This is not necessarily the most likely rate of warming – rather, it is a level of warming considered sufficiently likely to warrant consideration in the context of a risk assessment. This likelihood is judged on the basis of two factors:

- i) Future global emissions in the absence of stronger action on climate change mitigation.
- ii) The response of the climate system to those future emissions.

Both of these contributions to future warming are subject to substantial uncertainties.

Quantifying future emissions in the absence of stronger climate mitigation action is challenging and subject to high uncertainty, and is also subject to ongoing change in context. Although estimates of such emissions are routinely made (United Nations Environment Programme, 2020; Climate Action Tracker, 2021), these are intended to provide a systematic means of comparing the implications of new international commitments as a tool for monitoring progress on mitigation policy rather than providing information for risk assessments<sup>3</sup>. For a risk assessment such as CCRA3, a more comprehensive assessment of the range of potential outcomes is required.

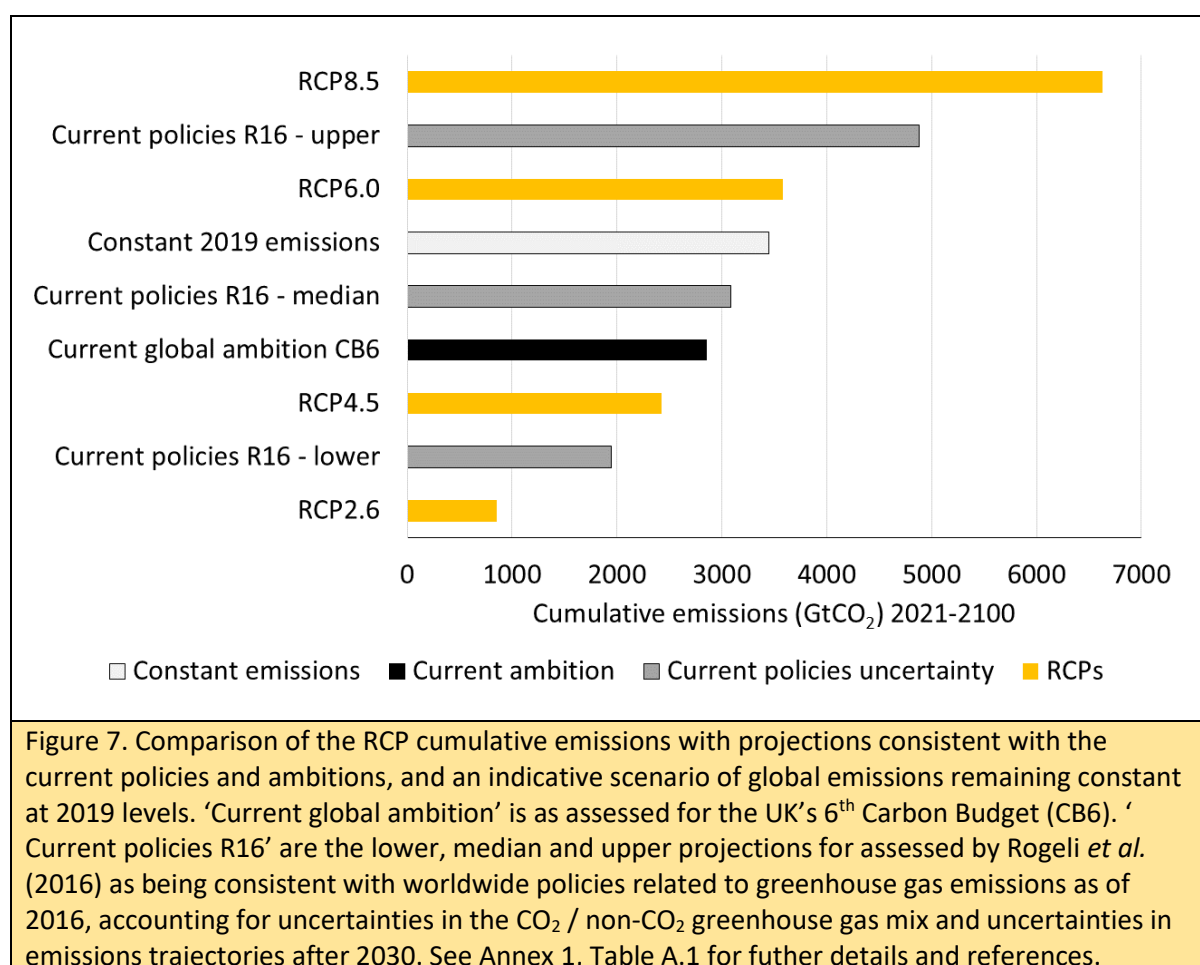

Predictions of political, economic, technological and societal futures are inherently deeply uncertain, and risk assessments need to consider the implications of this uncertainty. Moreover, with new national commitments on emissions being announced regularly, central estimates of future emissions trajectories require regular updates.

---

in UKCP18, and (ii) concentration pathways, as input to atmosphere-ocean models which do not make carbon cycle calculations, as in the CMIP5 models. This distinction is important as it can affect the projected rates of  $\text{CO}_2$  rise (Booth et al., 2017) and consequent rate of global warming (Hausfather and Betts, 2020). The same names are commonly applied to both uses. To distinguish between these two uses, the CCRA3 Technical Report adds “emissions scenario” and “concentrations pathway” after the RCP name.

<sup>3</sup> For example, the Climate Action Tracker (2021) uses a simple climate model and presents uncertainties in future global warming between the 16th and 84th percentiles of the probability distribution. CCRA3 uses the UK Climate Projections which are based on a number of climate models constrained against observed climate change, and considers the 5<sup>th</sup> to 95<sup>th</sup> percentile uncertainty range.

If emissions remain at current levels<sup>4</sup> from 2021 until 2100, cumulative CO<sub>2</sub> emissions would be approximately 3400 Gigatonnes (GtCO<sub>2</sub>). If pre-2020 Nationally Determined Contributions (NDC) commitments are implemented by 2030 and then decarbonisation continues at the same rate, cumulative emissions would reduce to approximately 2900 Gigatonnes (Vivid Economics and UCL, 2020). However, while the near-term trajectory of global fossil fuel emissions can be projected with some degree of confidence, uncertainties are much higher for emissions trajectories beyond the next one to two decades (Rogeli *et al.*, 2016). Considering currently implemented policies in 2016 (as opposed to NDCs, which are merely commitments), cumulative emissions from 2021 to 2100 range from approximately 2000 to 4900 GtCO<sub>2</sub>, with a median of approximately 3100 (Figure 7: Rogeli *et al.*, 2016)<sup>5</sup>. Therefore, rather than basing the risk assessment on a single best estimate of future emissions, a range of potential emissions needs to be considered.

The UKCP18 climate projections are driven by emissions scenarios associated with the Representative Concentration Pathways (RCPs). Of these, the cumulative emissions associated with RCP4.5 and RCP6.0 are within the range consistent with current policies (Figure 7). The RCP8.5 emissions scenario is above the upper end of the current policies range (Hausfather and Peters, 2020) and RCP2.6 is below the lower end.

<sup>4</sup>Total anthropogenic emissions of 43 GtCO<sub>2</sub> per year in 2019, including fossil fuel use, land use change and cement production. While emissions were lower in 2020, they have returned to approximately 2019 levels in early 2021.

<sup>5</sup> Projected cumulative emissions for 2011-2100 (Rogeli *et al.*, 2016), minus historical cumulative emissions 2012-2020 (Friedlingstein *et al.*, 2020)

For a risk assessment, it is not necessary to capture the full range of possibilities consistent with current trajectories: the focus is naturally on the higher end of the full set of possibilities. To provide such a focus while allowing a usefully large set of relevant literature to be considered, the CCRA3 higher warming pathway is defined as the range between the 50<sup>th</sup> and 95<sup>th</sup> percentiles in the UKCP18 projections driven by RCP6.0 emissions. The 50<sup>th</sup> percentile of the global annual temperature anomaly exceeds 3.5°C global warming by 2100 of the century, and the 95<sup>th</sup> percentile reaches 4°C global warming in 2080 and nearly 5°C in 2100 (Figure 6). Emissions trajectories in the upper part of the range consistent with current policies therefore bring a substantial likelihood of global warming exceeding 4°C within this century – nevertheless, it is not the most likely outcome, especially since emissions lower than RCP6.0 are also consistent with current policies. The 50<sup>th</sup> to 95<sup>th</sup> percentile range with RCP6.0 emissions includes projections used in a wide pool of literature with impacts projections applicable to a scenario of approximately 4°C warming in the late century, including studies that used previous generations of scenarios such as those from the IPCC Special Report on Emissions Scenarios (SRES: Nakićenović, *et al.*, 2000).

It is important to note that many impacts will continue to increase in magnitude after 2100, especially if warming is still ongoing at that time. Even if warming is limited to approximately 2°C, sea level rise is projected to continue due to ongoing melting of land ice and thermal expansion of ocean waters – with an extended RCP2.6 scenario, global sea level rise could reach over to 2m by 2300 (Palmer *et al.*, 2018). Higher emissions scenarios are projected to lead to larger rises. The implications of these longer-term risks are not explored in CCRA3 because the aim is to assess the urgency of adaptation, but they provide additional context on the benefits of mitigation.

The timing of reaching a particular climate state is a crucial element for informing adaptation. The CCRA3 Technical Report assesses risks in the 2050s and 2080s on pathways to levels of global warming of 2°C and 4°C at the end of the century.

The above pathways to 2°C and 4°C global warming are broadly representative of climate futures with and without further international action on mitigation, so comparison of the assessed magnitudes of the risks on each of these pathways could be considered to be approximately indicative of the reduction in UK climate risks by meeting the Paris Agreement objectives as imprecisely defined above. However, it is emphasised that this is not the primary purpose of the CCRA3 method and should not be interpreted as a rigorous assessment of the benefits of mitigation.

#### 2.4.4 Higher rates of global warming as part of the Low Likelihood High Impact assessment

In order to provide the widest possible context for assessment of adaptation urgency, the CCRA3 Technical Report also includes a general, less detailed consideration of low likelihood, high-impact outcomes, including rates of global warming faster than that reaching 4°C in 2080. Such rapid warming could arise if emissions grew along a pathway higher than those consistent with current policies, or from emissions consistent with current policies if feedbacks in the climate system are stronger than in the projections used here. The latter may require the passing of one or more tipping points in the climate system, most of which are considered to be of low likelihood but highly

consequential if they were to be passed. Chapter 1 (Slingo, 2021) describes some of these tipping points and their potential implications for climate change in the UK.

The above categories of Low Likelihood High Impact (LLHI) scenarios are not examined in detail for each risk but are addressed in a general way in each chapter. Chapter 2 provides further details, including definitions of which climate projections are included in the main analysis and which are LLHI high warming scenarios.

## 2.5 Current and future socioeconomic context for CCRA3

With risk consisting of hazard, vulnerability and exposure, the latter two components depend on socioeconomic factors and can also be modified by adaptation. CCRA3 uses information on current and planned levels of adaptation to assess whether there is shortfall and assesses the benefits of additional adaptation to assess the urgency of action.

The needs and capacity for adaptation can be strongly influenced by the socioeconomic context. Net Zero has the potential to influence the exposure and vulnerability components of many of the risks assessed in CCRA3, since all sectors of the economy will be involved in the transition to Net Zero. Although detailed, specific information on Net Zero socioeconomic pathways is not yet available, the Climate Change Committee's assessment of potential Net Zero approaches (Climate Change Committee, 2019) provides broad information that is used in CCRA3 to make a first estimate of the implications for adaptation needs, potential and urgency.

During the course of conducting the CCRA3 assessment, socioeconomic conditions in the UK and around the world have suddenly been impacted by the Covid-19 pandemic. As well as potentially being influenced by the direct economic impact of the nationwide and near-global "lockdown" situations, the socioeconomic components of climate risks may also be influenced by measures and policies that may be designed to reinvigorate the economy. At the time of preparing the report, the implications of the pandemic for exposure, vulnerability and capacity for climate adaptation were only just beginning to emerge. They are included in the risk assessment to the extent that is possible, but this can only be regarded as preliminary.

## 2.6 UK and international perspectives

As well as assessing the risks and opportunities that climate change poses directly to the UK via potential impacts within its own geographical locality, CCRA3 follows CCRA2 in assessing the implications for the UK of current and potential climate change impacts elsewhere in the world. These international dimensions of climate change risk to the UK can include supply chains for food and other goods, migration and displacement, and security issues including the potential for conflict and humanitarian responsibilities. Both local and international risks and opportunities addressed in the assessment were selected through a process of consultation with stakeholders across various government departments.

### 3. Sources of evidence for CCRA3

#### 3.1 Evidence from the literature

A major source of information for CCRA3 is the literature in both peer-reviewed academic journals and non-academic reports from relevant organisations. The latter are often particularly important as sources of evidence on current and planned adaptation, and these are considered in the assessment if they have been subject to independent review.

While much of this evidence was brought in to the CCRA3 process through the knowledge of the literature of the author teams, further evidence was obtained via three open calls for evidence and through the review process. When assessing the magnitude of future risks, studies in the literature used climate projections from a large number of models with a variety of different emissions or concentrations scenarios. Wherever possible, the assessment used studies with projections aligning to the CCRA3 lower and higher scenarios of approximately 2°C and 4°C global warming at the end of the 21<sup>st</sup> Century, as defined in Section 2.3. Where the only available studies used projections with warming rates outside of the specified ranges of these pathways, expert judgement was used to establish the implications for changes within those pathways.

#### 3.2 New research for CCRA3

In addition, some research has been carried out specifically to feed into CCRA3, in order to address key knowledge gaps identified following CCRA2 and ensure that priority areas are informed by the most up-to-date evidence. Some of this was commissioned as part of the CCRA3 process, and some emerged from other research programmes such as the Met Office Hadley Centre Climate Programme and the Strategic Priorities Fund UK Climate Resilience programme of UKRI and the Met Office. Further details are provided in Chapter 2 (Watkiss and Betts, 2021).

#### 3.3 Using the latest UK Climate Projections

An important issue for the CCRA process is ensuring that the risk assessment considers all relevant climate projections, including the most recent, state-of-the-art projections. The latest set of UK Climate Projections (UKCP18; Lowe *et al.*, 2018) were published in 2018 with further components released in 2019 and 2020 and have been extensively used in the CCRA3 Technical Report and the research upon which it draws. UKCP18 global-scale probabilistic projections (Murphy *et al.*, 2018) have been used for defining the higher and lower scenarios of warming for framing the assessment of future risk magnitudes, as described in Section 2.3. The UK-scale probabilistic land projections (Murphy *et al.*, 2018), perturbed-parameter global and regional projections (Murphy *et al.*, 2018) and marine projections (Palmer *et al.*, 2018) underpinned the CCRA3 research carried out in support of the Technical Report (see Chapter 2; Watkiss and Betts, 2021), which directly informed the assessment of a number of risks. The high-resolution local projections (Kendon *et al.*, 2019) provided further context through the provision of improved assessment of extreme weather events, against which the conclusions of other research could be compared.

Not all risks were directly informed by UKCP18 because it can take some time – many months, and often years – for new projections to be used in scientific studies and for the results to be published in the peer-reviewed literature. To check the robustness of conclusions based on older projections, key results from UKCP18 were compared with equivalent results from the previous projections from UKCP09 (Murphy *et al.*, 2009) (Johns *et al.*, 2021).

The main focus was on aspects of the projections that used emissions scenarios that represent trajectories to approximately 2°C or 4°C global warming in the late 21<sup>st</sup> Century, as described in Section 2.3. Although the scenario of 4°C warming by the end of the century has been defined on the basis of the RCP6.0 emissions scenario, the range of results for the probabilistic projections overlap to some extent between the RCP, so some percentiles of other scenarios can also fall within the definition of the pathway to 4°C warming by the end of the century. For example, as well as including a large proportion of UKCP18 projections with RCP6.0 emissions, the 4°C warming scenario also includes the upper end of projections RCP4.5 emissions that warmed relatively fast due to high climate sensitivity. It also included the lower end of projections with RCP8.5 emissions that warmed relatively slowly due to low climate sensitivity (see for example Sayers *et al.*, 2020 and Arnell *et al.*, 2021).

In some cases, information relevant to 4°C global warming was only available from components of the UKCP18 that reached this level of warming faster than in the CCRA3 higher scenario, such as the majority of projections driven by the RCP8.5 emissions scenario. Where this involves quantities known to scale linearly with global warming levels, such as many aspects of extreme weather (Wartenberger *et al.*, 2017), it can be appropriate to treat such changes as representative of the regional climate state reached at the same level of warming at a later time (Bärring and Strandberg, 2018). In these cases, the changes projected at 4°C global warming were therefore applied to a later date within the range of the CCRA3 higher scenario (see for example HR Wallingford, 2020). This method was not applied for quantities which are strongly dependent on the rate of warming rather than its instantaneous magnitude, such as sea level rise. Higher-warming RCP8.5-based projections were also used to inform the general assessments of Low Likelihood High Impact scenarios described above.

## 4. Overview of the Technical Report chapters

Chapter 1 (Slingo, 2021) provides the climate science context for the risk assessment. It presents an update on observed climate change in the UK and across the world, including changes in the long-term climate state and extreme weather events and seasons. It provides a summary of the extent to which these changes are attributable to human-caused climate change and hence would be expected to increase further as human influence continues to grow. This is important information in the context of informing assessments of near-term risks. Since specific projections of the future consequences of current policies and global Paris-compliant policies are not available, Chapter 1 presents information available from the latest projections illustrating potential outcomes of these two categories of emissions futures. Chapter 1 also includes an overview of the implications for the standard projections of passing climate systems tipping points.

Chapter 2 (Watkiss and Betts, 2021) describes the methodology of the risk assessment and the steps taken by the authors in assessing the magnitude of risks, the effectiveness of current and planned adaptation and the benefits of additional action in the next 5 years, in order to assign the Urgency Score for each risk. Chapter 2 also summarises some of the key developments in evidence and understanding since CCRA2 was published, including lessons from other international risk, lessons learned from the CCRA2 process itself, and new understanding in climate science and adaptation, including improved evidence on vulnerability, exposure and adaptive capacity. It also includes a summary of the new or improved aspects of the CCRA3 method compared to CCRA2.

Chapters 3 to 7 present the assessment of risk and opportunity to the UK broadly categorised by general areas of policy or societal interest which illustrate how climate change is affecting all aspects of life in the nation. Natural Environment and Assets (Chapter 3: Berry and Brown, 2021) covers ecosystems, biodiversity, agriculture and the rural landscape, including the cultural landscape. Infrastructure (Chapter 4: Jaroszweski, Wood and Chapman, 2021) represents the physical assets that humans have constructed to support a modern, functioning society by providing protection from the elements, supplies of energy and water, and to facilitate transportation. Human Health, Communities and the Built Environment (Chapter 5: Kovats and Brisley, 2021) includes well-being, culture and homes of people as individuals or groups. Business and Industry (Chapter 6: Surminski, 2021) represents the economic operation of the country, and International Dimensions (Chapter 7: Challinor and Benton, 2021) reflects the critical, close relationship between the UK and the rest of the world. All these aspects of UK life are sensitive to weather and climate and have evolved or been designed in the context of historical conditions.

Chapters 3 to 7 represent risk categories that are identical to those in CCRA2 so provide continuity. However, some chapter titles have been updated to better highlight key areas of focus.

## Annex 1. RCP emissions scenarios and projections consistent with current policies and ambitions.

**Table A.1** Projections of cumulative emissions from 2021 to 2100 for pre-2020 NDC commitments, and current policies as of 2016 with uncertainties, compared with the RCPs. RCP data are from <https://tntcat.iiasa.ac.at/RcpDb/dsd?Action=htmlpage&page=compare>. Rogeli *et al.* (2016) (R16) provide 'Current policies' cumulative emissions for 2011 – 2100, from which cumulative emissions from 2021-2100 were derived by subtracting cumulative emissions from 2011-2020 (Friedlingstein *et al.*, 2020)

Emissions scenario / projection	Description	Reference	Cumulative emissions 2021 – 2100 (GtCO <sub>2</sub> )
RCP8.5	Standard emissions scenario associated with the RCP8.5 concentrations pathway.	van Vuuren <i>et al.</i> , (2011)	6629
Current Policies R16 – upper bound	Upper estimate of CO <sub>2</sub> emissions consistent with worldwide policies related to greenhouse gas emissions as of 2016, accounting for uncertainties in the CO <sub>2</sub> / non-CO <sub>2</sub> greenhouse gas mix and uncertainties in emissions trajectories after 2030.	Rogeli <i>et al.</i> , (2016)	4879
RCP6.0	Standard emissions scenario associated with the RCP6.0 concentrations pathway.	van Vuuren <i>et al.</i> , (2011)	3585
Constant emissions	Emissions remain at 2019 levels from 2021 to 2100.	Friedlingstein <i>et al.</i> (2020)	3446
Current Policies R16 – median	Median estimate of CO <sub>2</sub> emissions consistent with worldwide policies related to greenhouse gas emissions, as of 2016.	Rogeli <i>et al.</i> , (2016)	3090
Current Global Ambition CB6	Pre-2020 NDC commitments around the world in 2030 and continue to decarbonise at this same rate (changes in emissions intensity of GDP) after 2030. Prepared for the UK's 6 <sup>th</sup> Carbon Budget (CB6)	Vivid Economics and UCL (2020)	2855
RCP4.5	Standard emissions scenario associated with the RCP4.5 concentrations pathway.	van Vuuren <i>et al.</i> , (2011)	2423
Current policies R16 – lower bound	Lower estimate of CO <sub>2</sub> emissions consistent with worldwide policies related to greenhouse gas emissions as of 2016, accounting for uncertainties in the CO <sub>2</sub> /non-CO <sub>2</sub> greenhouse gas mix and uncertainties in emissions trajectories after 2030.	Rogeli <i>et al.</i> , (2016)	1950
RCP2.6	Standard emissions scenario associated with the RCP2.6 concentrations pathway.	van Vuuren <i>et al.</i> , (2011)	853

## Key Messages

This chapter considers the latest observations of, and future projections for, the changing climate in the UK and across the globe. In particular, this chapter focuses on new projections of climate change arising from developments in climate modelling since the 2<sup>nd</sup> Climate Change Risk Assessment (CCRA2) in 2017. These developments allow for a more comprehensive assessment of future UK and global climate changes, including those which might alter, materially, the range of risks and opportunities in the various sectors of this assessment compared to previous projections.

This chapter uses the term ‘climatic impact drivers’ to refer to changes in aspects of UK and global weather and climate (e.g., precipitation, temperature, etc). This distinguishes projected changes in aspects of the UK’s weather and climate from the hazards and opportunities that they drive (e.g., heavy rainfall changes driving changes in flooding hazard in some instances). This chapter also puts greater emphasis than in CCRA2 on assessing the variability of the UK’s weather and climate, and how this variability might change as the planet warms.

The main conclusions of this chapter are:

- 1. Since CCRA2 in 2017, the world has continued to warm with effects on UK and global weather and climate becoming more evident and increasingly attributed to human-induced climate change.** Temperature and sea level rise are the clearest signals of a changing climate for the UK. There is a growing body of evidence suggesting increases in mean rainfall, particularly in winter, and down the west side of the UK. The evidence base for whether UK storminess will change remains weak and should be addressed as a priority for future research.
- 2. New UK weather and climate records are being set more frequently, with the UK experiencing unprecedented high temperatures and heavy rainfall.** Extreme events test resilience and preparedness, and there is increasing evidence that, even today, human influences have changed and continue to change the likelihood of weather and climate extremes. New science since CCRA2 has highlighted that unprecedented extreme weather events are possible even in today’s climate; for example, there is currently a 1% chance every year that monthly winter UK rainfall can be 20-30% higher than the maximum observed.
- 3. The UK is projected to experience ongoing increases in temperature until the middle of the 21<sup>st</sup> Century under all scenarios for future global climate change, including those approximately consistent with achievement of the goal of the Paris Agreement to limit global warming to well below 2°C.** Until the middle of the century, the extent and spatial pattern of UK climate change depends more on regional climate and weather responses to global warming than the level of future global greenhouse gas emissions.
- 4. From the 2050s onwards, higher emissions scenarios are projected lead to greater increases in extreme weather and sea level both at UK and global scales.** In a high scenario by 2080, 40°C is projected to be exceeded as frequently as 32°C is exceeded today. At the time of this assessment 40°C has not yet been reached in the UK, but could occur with a return time of 3.5 years by the end of the century in a high-warming scenario.

5. **The severity of extremes is projected to increase with global warming.** Meteorological, agricultural and hydrological droughts are expected to become more severe with implications for water resource management. An increase in the incidence of high summer daytime temperatures throughout the UK. In the future, Scotland and Northern Ireland could start to see high summer temperatures similar to those of England and Wales currently. All parts of the UK will continue to experience a steady reduction in frost days as global warming increases, although some years will still see similar numbers of frost days and cold-related impacts as in recent years.
6. **Future summers are projected to be even hotter and drier than earlier estimates in CCRA2, for equivalent levels of global warming.** Based on the new Met Office models in the UK Climate Projections 2018 (UKCP18), reductions in future rainfall are substantially larger over England, typically double those used in CCRA2. This is due to improved simulations of summer circulation anomalies and their impacts on rainfall, as well as higher temperatures. However, year-to-year variations in summer rainfall indicate that while drier summers are generally more likely across the UK, wetter summers are also possible. Furthermore, despite overall summer drying, with wet days projected to become less frequent, the new kilometre-scale projections suggest that when it does rain, the daily rainfall will be more intense by as much as 20%, relative to coarser models.
7. **We can expect more frequent and more severe extreme daily high temperatures and Urban Heat Island effects even though the mean warming is almost identical.** Better representation of the landscape and urban areas in the kilometre-scale model have highlighted that there is a very small chance (less than 0.02%) of exceeding 40°C by 2040, but by 2080 the frequency of exceeding 40°C is similar to the frequency of exceeding 32°C today. Urban heat island intensity will increase during both day and night, but new results have shown greater increases in night-time intensities implying significantly more 'tropical nights'. During summer, night-time temperatures in the urban areas of 10 major cities will increase significantly, at rates between 0.48 and 0.55°C per decade during the 21<sup>st</sup> century.
8. **New kilometre-scale projections show pronounced shifts to more intense hourly rainfall at the expense of lighter rainfall, compared with coarser models as used in CCRA2.** For example, summer hourly extremes of 20mm/hour may occur twice as frequently as previously projected. Furthermore, there is new evidence on the frequency of rainfall exceeding 30mm/hour for some UK cities, showing that such events are twice as likely by 2080.
9. **Winter extreme rainfall is projected to be around 40% more intense compared to CCRA2, with future winters becoming warmer and wetter overall.** New kilometre-scale projections from UKCP18 shows that physical processes not resolved in the coarser regional and global models increases projections for future winter rainfall by around 40% relative to previous projections. They also show that daily rainfall intensity is projected to increase by as much as 25% relative to coarser models, particularly in the south-east.

- 10. Future winter weather is projected to be dominated by more mobile, cyclonic weather systems than was the case in previous assessments.** This will affect the western parts of the UK, in particular, and reinforces the evidence for more substantial increases in daily rainfall with related flooding, as well as a higher incidence of strong winds and waves. The projected shift to more mobile, cyclonic winters may also increase the risk of atmospheric river events that bring large amounts of rainfall and are major contributors to severe flooding and landslides, particularly for the mountainous regions of the UK.
- 11. The increase in rainfall intensity and mobility of cyclonic weather patterns arise from improvements in climate modelling.** Although the HadGEM3-GC3.05 model used for these components of the UKCP18 projections has a very high climate sensitivity, these results for rainfall intensity and storminess are not related to that process. The UKCP18 probabilistic projections do not use HadGEM3-GC3.05 – instead, they use the same base model as the UKCP09 projections, plus a wider consideration of the large set of multi-model projections in the 5<sup>th</sup> Coupled Model Intercomparison Project (CMIP5). The UKCP18 probabilistic projections warm faster than the CMIP5 projections because they include uncertainties in carbon cycle feedbacks.
- 12. New estimates of global sea-level rise indicate an additional 5 - 10cm rise by 2100 compared with CCRA2 estimates.** These include a contribution from Antarctic ice dynamics. These faster projections of sea level rise are due to improved understanding and modelling of land ice processes, not faster warming due to higher climate sensitivity, because the new sea level projections are being driven by the CMIP5 projections rather than the UKCP18 land projections.
- 13. Low-likelihood, high-impacts scenarios are considered in CCRA3.** The new regional projections warm faster than those used in CCRA2, partly due to high climate sensitivity in the global model, and partly due to the use of a higher emissions scenario. Therefore the timing of these regional changes should not be considered the most likely outcome but factored into planning as a lower probability high risk future. In the most extreme sea level scenarios, global sea-level rise could reach 2m by 2100 but this is viewed as very unlikely and with low confidence. However, the processes behind ice sheet collapse particularly for Antarctica remain very uncertain and continued monitoring and process studies are vital.

Scientific advances since CCRA2, along with the delivery of UKCP18 and the development of a new generation of climate models, have provided new and important evidence regarding expected changes in the UK's weather and climate. This chapter summarises a significant body of new evidence on projected changes in the UK's weather and climate that will help improve assessment of future climate risks and opportunities. In particular, the most up-to-date and physically comprehensive projections indicate that future changes may be more extreme than previously projected in CCRA2, especially locally and on daily timescales. In some areas, important knowledge gaps remain, for example, further research is required to test the robustness of projections in changes in storminess.

## 1.1 Introduction

This chapter summarises the latest scientific evidence on current and future climate change, including new advances made since the second climate change risks assessment (CCRA2), which either consolidate previous understanding or bring new insights. These assessments will be placed in the context of global changes, especially where these changes may have a material impact on the UK.

CCRA2 drew on literature assessing future climatic impact drivers for the UK and worldwide based mainly on the United Kingdom Climate Projections 2009 (UKCP09) and the global projections published in the IPCC Fifth Assessment Report (AR5). These projections have also informed much of the literature available for assessment in CCRA3.

Whilst the IPCC Sixth Assessment Report (AR6) has not yet been published, a new set of UK Climate Projections (UKCP18) has been published since CCRA2. These projections draw on significant advances in model development since the earlier UKCP09 and IPCC AR5, as well as research conducted in preparation for the creation of new sets of climate projections in the 6<sup>th</sup> Coupled Model Intercomparison Project (CMIP6). CMIP6 underpins the IPCC 6<sup>th</sup> Assessment Report, due to be published in July 2021.

This chapter will focus specifically on identifying significant differences in the climate science evidence base from UKCP09 and CCRA2, drawing on the results from UKCP18 in particular. Since CCRA2 there have been important scientific advances across a number of fronts:

- Extended observational records through data archaeology and improved global and regional reanalyses, including additional recent observations during a time of global warmth unprecedented in the observational record.
- Ongoing detection and attribution of climate change trends in the observational record, and the rapidly developing methodologies for attributing extreme events to human-induced climate change.
- New global and UK regional projections based on improved modelling systems with higher resolution and better representation of climatic impact drivers, especially associated with climate variability, weather systems and local extremes.
- Greater overall understanding of the climate system, its response to forcing, and the potential for accelerating Earth system feedbacks and abrupt changes.

It is widely recognised that some of the more costly, disruptive and dangerous impacts of climate change will be associated with increased frequency and/or intensity of extreme weather and climate events. The UK's weather and climate are highly variable because of where the country sits on the globe - at the end of the North Atlantic storm track where cold polar and warm sub-tropical air masses collide, and with maritime influences from the ocean to the west, and continental influences from Europe to the east. These factors make detecting, attributing, predicting and projecting changes in UK's weather and climate, especially for more extreme events, challenging, but vitally important.

Consequently, this chapter puts greater emphasis on assessing the variability of the UK's weather and climate, how this variability might change in terms of frequency and/or intensity as the planet warms, and what this means for unprecedented extremes and their impacts. This has been made possible by significant advances in global and regional climate modelling and their applications since

UKCP09 and CCRA2, with current climate models now able to capture regional and local weather with greater fidelity. These advances are documented in Annex 1 and include significant increases in global model resolution for both the atmosphere (60km spacing between grid cells, reduced from 150km in CCRA2) and oceans (0.25° from 1° in CCRA2), improvements in the model physics, increases in regional model resolution from 25km to 12km, and the deployment of a new kilometre-scale UK regional model.

Although the socio-economic impacts of climate change will be felt more keenly through extreme weather and climate events, the natural environment is also susceptible to longer-term trends in the climate, such as shifts in the regular seasonal weather and climate conditions, which affect phenology, habitats and survival of species. These impacts may only come into play, or become serious, when certain meteorological thresholds are exceeded. Consequently, as part of CCRA3, additional analysis of UKCP18 has been carried out to provide information on, firstly, the changes to weather and climate variability and extremes, and secondly, on trends in climatic indices that affect the natural environment.

## 1.2 Our approach to assessing the new climate science that underpins CCRA3

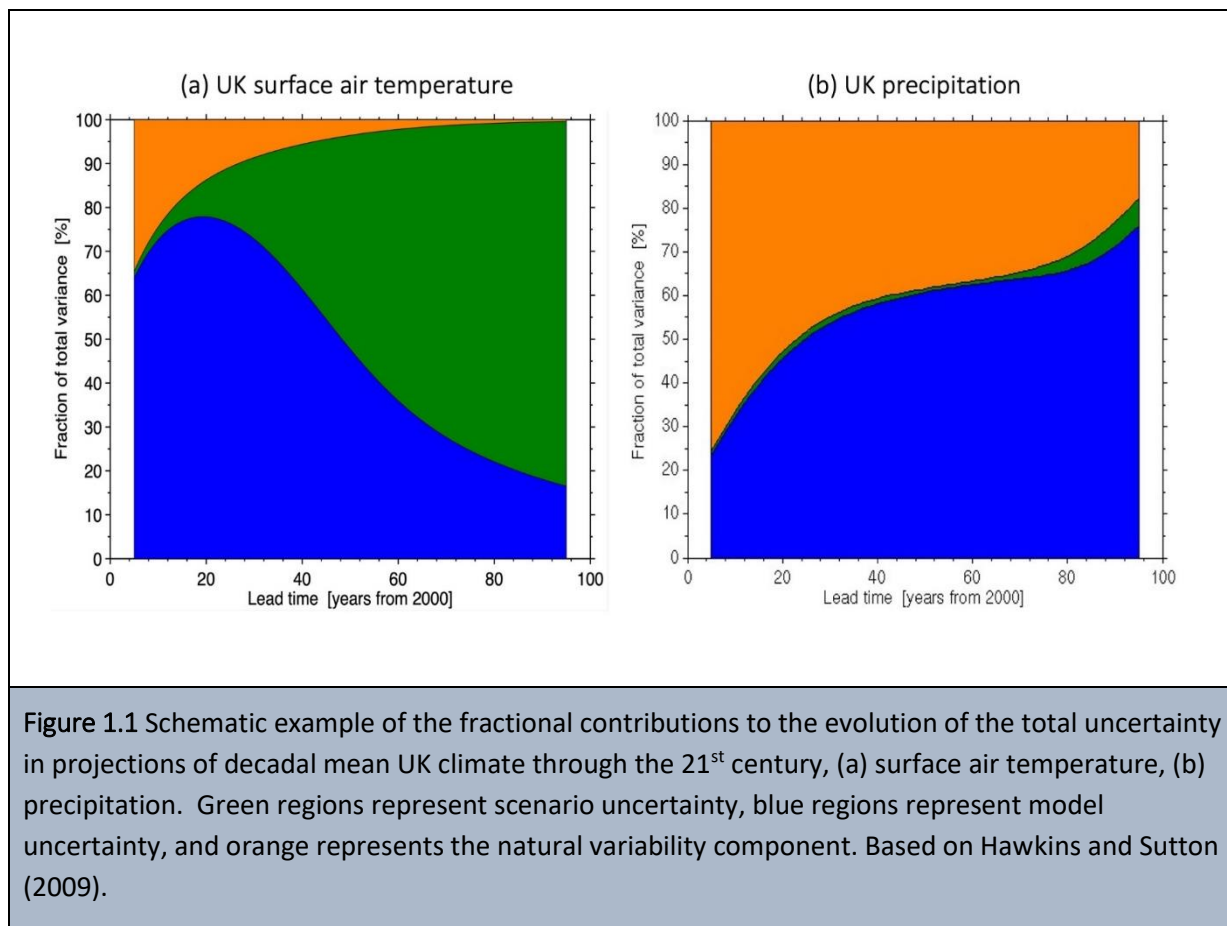

As with the sectoral chapters and documented in Chapter 2, the approach here is to integrate existing information from the literature base and previous projections, with new projections and other new research. UKCP18 has provided important new evidence and much of the chapter will focus on how this has evolved our understanding of the UK's future climate. CCRA3 uses all the UKCP18 products to some extent, mainly the probabilistic projections and HadGEM3 global projections, but also the regional and local projections where possible.

### 1.2.1 Representing uncertainty in the new UKCP18 projections

It is essential that we consider the uncertainty in the climatic impact drivers by looking at the various sources of uncertainty, how they evolve with time through the 21<sup>st</sup> century (Figure 1.1 based on Hawkins and Sutton, 2009), and how well the various ensembles of global and regional projections are able to sample the range of possible outcomes. It is also important to understand that different climatic impact drivers have different sources of uncertainty. As Figure 1.1(a) shows, surface temperature change is dominated by natural (internal) variability<sup>1</sup> for the first 2 decades whilst the uncertainty due to the global emission scenarios remains relatively small. For the latter half of the century, the uncertainty is increasingly dominated by the global emission scenarios. Model uncertainty, associated for example with cloud feedbacks, is important throughout. On the other hand, for precipitation (Figure 1.1(b)), natural variability plays a significant role at all lead times whilst scenario uncertainty barely enters the assessment.

---

<sup>1</sup> Natural variability describes the variations in weather and climate that we experience from day-to-day, year-to-year and decade-to-decade. They occur due to internal processes in the climate system associated with the atmospheric (such as weather patterns) and oceanic circulation (such as El Niño). They also include intermittent impacts from explosive volcanic eruptions and associated cooling by aerosols.

The UKCP18 projections include a number of components using different sets of models and different approaches to quantifying or exploring uncertainty (Murphy *et al.*, 2018):

- (i) the probabilistic land projections (at UK and global scales) with a range of emissions scenarios.
- (ii) perturbed-parameter ensembles of global, regional and local projections (at resolutions of 60km, 12km and 2.2km respectively) with a very high emissions scenario
- (iii) derived projections representing long-term climate states at 2°C and 4°C global warming and a low-emissions scenario
- (iv) marine projections.

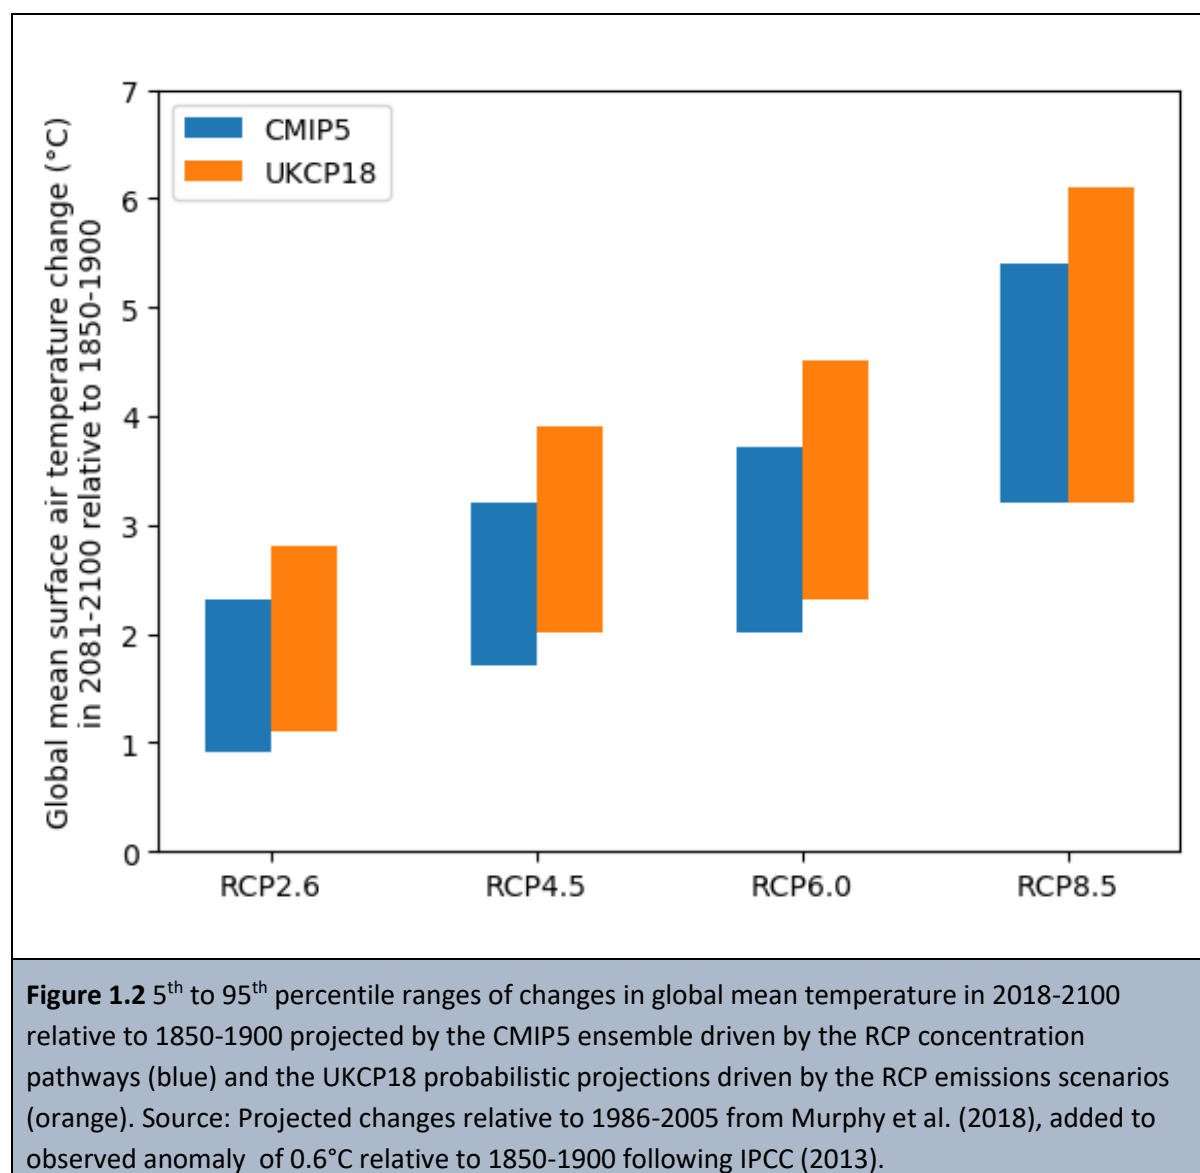

The probabilistic projections are based on the same climate model, HadCM3, as used in UKCP09, with additional information from the CMIP5 multi-model ensemble. These provide a comprehensive quantification of uncertainty, drawing on this very wide base of information including a large number of independent models. The global perturbed-parameter ensemble (PPE) uses the HadGEM3-GC3.05 climate model, and the regional and local ensembles use high-resolution limited area models taking boundary conditions from the global PPE. The derived projections use the HadGEM3-GC3.05 PPE and CMIP5. The marine projections use CMIP5, applying these to new models of sea level rise and other aspects of marine impacts. The use of different sets of models in the various strands of UKCP18 arose from the need to carry out developments in all strands in parallel. The final set of projections are all useful for different aspects of climate change risk assessment and are all used in CCRA3 in various places. Since they use different models and different

approaches, use of several strands together requires an awareness of potential inconsistencies. The following chapters in the CCRA3 Technical Report make clear which UKCP18 strands have been used, and also whether other sources of climate projections have been used.

UKCP18 uses emissions scenarios linked to the Representative Concentration Pathways (RCPs), with an important feature being the representation of uncertainties in carbon cycle feedbacks. This contrast with the CMIP5 ensemble, in which all models are driven by the same concentration pathway for CO<sub>2</sub> and other greenhouse gases (see Annex 1 section A1.4 for discussion of the important difference between the RCPs used as Concentration Pathways and Emissions Scenarios). The probabilistic projections considered four RCP scenarios, ranging from RCP2.6 (which is consistent with extensive mitigation of emissions) through to RCP8.5 (which has future emissions considerably higher than pathways considered consistent with current worldwide energy policies). The intermediate scenarios RCP4.5 and RCP6.0 were also included: these are within the range of possible emissions futures considered consistent with current worldwide policies. In CCRA3, RCP6.0 is used to define the higher climate change scenario used for the risk assessment. Many, but not all, projections with RCP8.5 are considered as low-likelihood, high-impact outcomes and not included in the main assessment. Details of the use of the different emissions scenarios and concentration pathways are given in the Introduction chapter (Betts and Brown, 2021), and Chapter 2 (Watkins and Betts, 2021).

Comparing the UKCP18 global probabilistic projections at 2081-2100 relative to 1850-1900 with those from CMIP5 for the RCP scenarios, UKCP18 projects ranges of global warming which are systematically higher than those of CMIP5 (Figure 1.2). A major factor contributing to this difference is that the CMIP5 projections were driven by CO<sub>2</sub> concentrations from the standard RCP pathways, whereas UKCP18 used emissions scenarios associated with the RCPs, accounting for uncertainties in climate-carbon cycle feedbacks. For each emissions scenario, UKCP18 therefore represented the response to a range of CO<sub>2</sub> concentration pathways, most of which were higher than the standard pathways (Murphy *et al.*, 2018). Further details are given in Annex 1 section A1.4.

Due to the computational cost of the new high resolution regional simulations for UKCP18 (see Annex 1), the UK regional and local climate change scenarios were only produced using a single emission scenario to allow for the largest possible ensemble size to be utilized, in order to cover a wide range of regional climate responses. The highest emissions scenario, RCP8.5, was chosen so that the widest range of future levels of global warming could be explored, including the most extreme climate changes considered as low-probability, high-impact scenarios. This means that, unlike the probabilistic projections, the HadGEM3 global projections and associated regional and local projections are not available for RCP6.0, RCP4.5 and RCP2.6 which project slower rates of warming than RCP8.5. Nevertheless, for many climate impact drivers, the projected regional changes at particular levels of global warming can be considered to be representative of the same level of global warming reached at a later date with a lower emissions scenario and/or as a result of a lower climate sensitivity.

CCRA3 is framed in terms of trajectories of global warming rather than emissions scenarios. Research commissioned on some of the risks therefore used selected components of the UKCP18 projections representing global warming of approximately 2°C and 4°C at the end of the century. The assessment of other risks draws on literature using other models, projections and scenarios that give approximately 2°C and 4°C global warming by 2100.

### 1.2.2 Improved regional dynamics for the simulation of UK weather and climate in the new UKCP18 projections

Hazardous weather with the potential to cause harm, such as floods and heatwaves, have always occurred due to weather and climate variability, but their frequency and / or magnitude can be affected by anthropogenic climate change. Although climate change is often quantified in terms of global mean surface temperature (GMST), the impactful changes at local scales depend on complex responses of the climate system to greenhouse gas increases, and the interactions between these responses and the processes of climate variability (Sutton *et al.*, 2015). GMST primarily provides information about the level of aggregated global risks from climate change and is the main metric for efforts to reduce global emissions. On the other hand, understanding and quantifying natural variability and the complex response of the global circulation to anthropogenic warming is essential for projecting climatic impact drivers on regional to local scales.

The UK's weather and climate, especially precipitation, are dominated by natural variability and will continue to be so. In this regard, the position and variability of the North Atlantic Jetstream is of fundamental importance for determining the weather and climate of the UK, and its future behaviour will define many of our future climatic impact drivers.

The behaviour of the North Atlantic Jetstream is particularly complicated, compared, say, with the Pacific Jet. In winter, it has three preferred positions with each position corresponding to specific weather regimes – to the north of the UK (European Blocking), over the UK (positive North Atlantic Oscillation) and to the south of the UK (negative North Atlantic Oscillation). These regimes describe the tracks of storms and the development of blocking episodes, and essentially determine the frequency and/or intensity of windstorms, atmospheric rivers<sup>2</sup> and extreme frontal rainfall.

Consequently, a focus of this chapter is on how the North Atlantic Jetstream may behave in the future and what this means for the key weather regimes that define the UK's winter climate. To do this, it is important that global climate models can capture the three positions of the Jetstream described above, and to do it for the right reasons.

Since CCRA2, the Met Office has made significant advances in global and regional modelling for weather and climate prediction. A new climate model, HadGEM3, has been developed which features significant increases in horizontal and vertical resolution in the atmosphere and ocean, as

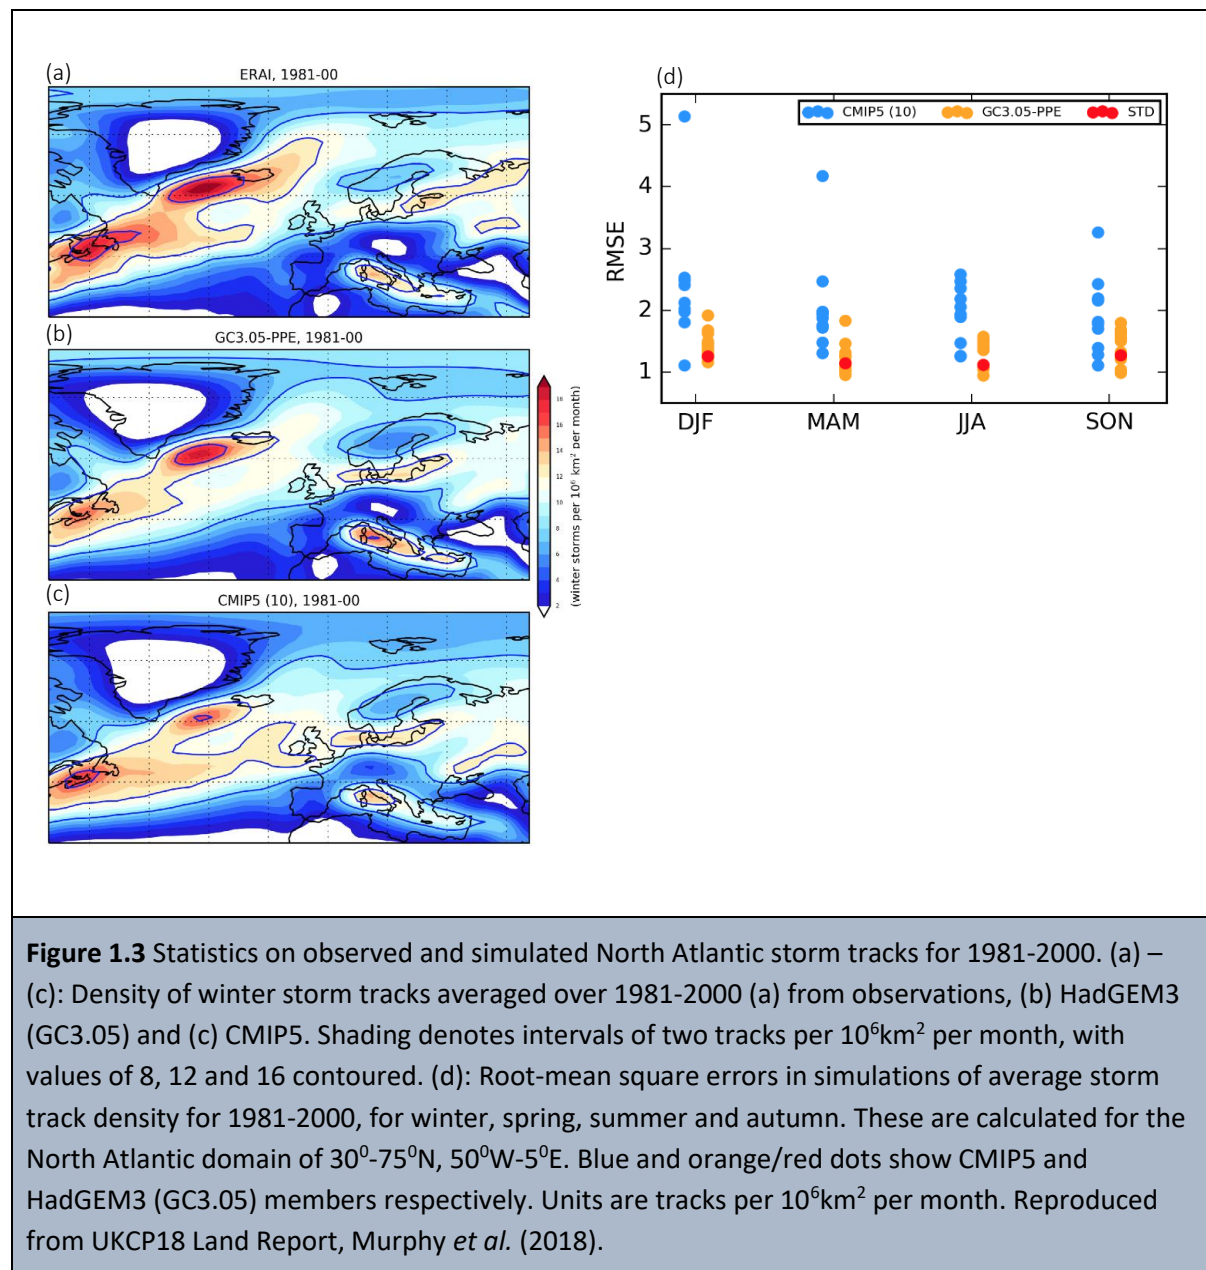

---

<sup>2</sup> Atmospheric rivers are relatively long, narrow regions that form on a strong jet stream and are characterized by intense moisture transport, which, on landfall, produce excessive precipitation that can lead to major flooding (e.g., Lavers *et al.*, 2011). Storms Desmond and Dennis in 2015 and 2020, respectively, are examples of atmospheric river events.

well as improvements in model physics (Williams *et al.*, 2018). The atmosphere model resolution increased from 150km in the horizontal, as used for CMIP5 and IPCC AR5, to 60km, and from 38 to 85 levels in the vertical. The ocean resolution increased from 1° to 0.25° and from 40 to 75 levels. These enhancements in resolution have delivered significant improvements in the structure of weather systems and ocean circulation, giving notable reductions in a number of key systematic model biases (Annex 1 and Figure A1.1 from Murphy *et al.*, 2018).

Of particular relevance to CCRA3, is the improvement in the simulation of the position and variability of the North Atlantic Jetstream in HadGEM3, and hence the weather systems that affect the UK (Figure 1.3). Figure 1.3 (a-c) shows the density of the tracks of winter storms over the North Atlantic for 1981 to 2000 from the observations (ECMWF Reanalyses) and from the ensemble means of the HadGEM3 (GC30.5-PPE) and CMIP5 simulations; Figure 1.3(d) provides a summary of the seasonal errors in simulated track density.

HadGEM3 reproduces observed winter storm track density quite well in general, whereas the CMIP5 models tend to underestimate the maximum south of Greenland and the observed extension to the north-east of Iceland is missing. Of particular relevance to CCRA3, the number of storms tracking across the UK and into Europe is overestimated in the CMIP5 models. Seasonal error statistics (Figure 1.3(d)) typically show a larger spread of errors for the CMIP5 models, and several CMIP5 members score worse than any of the HadGEM3 members, in each of the four seasons. One CMIP5 model shows root mean squared error (RMSE) values considerably larger than the other simulations in winter, spring and autumn, because the storm track is shifted south and is too zonally (east-west) oriented, with too many winter storms moving across the UK and western Europe. Further background information on the Jetstream in HadGEM3 and the CMIP5 models can be found in McSweeney and Bett (2020).

As part of major advances in seasonal to decadal prediction<sup>3</sup> using HadGEM3 (e.g., Scaife *et al.*, 2014; Smith *et al.*, 2019), there has been significant progress recently in understanding the global drivers of the UK's climate variability and associated weather regimes. These include the El Niño/Southern Oscillation (ENSO), drivers from the stratosphere such as stratospheric sudden warmings, and the patterns of sea surface temperatures in the North Atlantic. These advances play an important role in assessing how the global effects of climate change on phenomena, such as

<sup>3</sup> There is an important distinction between prediction and projection. Prediction starts from an observed initial state of the weather and climate system and aims to forecast how the climate system will evolve in the coming days to years (such as in numerical weather prediction and monthly to decadal climate prediction). Projection is simply a simulation of how the climate system might behave in response to changing imposed external forcings such as greenhouse gas and aerosol concentrations.

ENSO, might alter the population of the three positions of the Atlantic Jetstream shown in Figure 1.2 and hence on UK weather regimes. Improvements in predictability give us confidence that HadGEM3 has captured natural climate variability and its drivers more faithfully.

HadGEM3 is part of the comprehensive new set of UK climate projections (UKCP18) and other applications, including global forecasts on timescales of months to a decade ahead. The UKCP18 regional and local projections (see UKCP18 Science Reports – Murphy *et al.*, 2018; Palmer *et al.*, 2018; Kendon *et al.*, 2019), all used HadGEM3, with the boundary conditions<sup>4</sup> coming from variants of that model. As documented in detail in Annex 1, HadGEM3 brings some important benefits to our assessment of future climatic impact drivers for the UK.

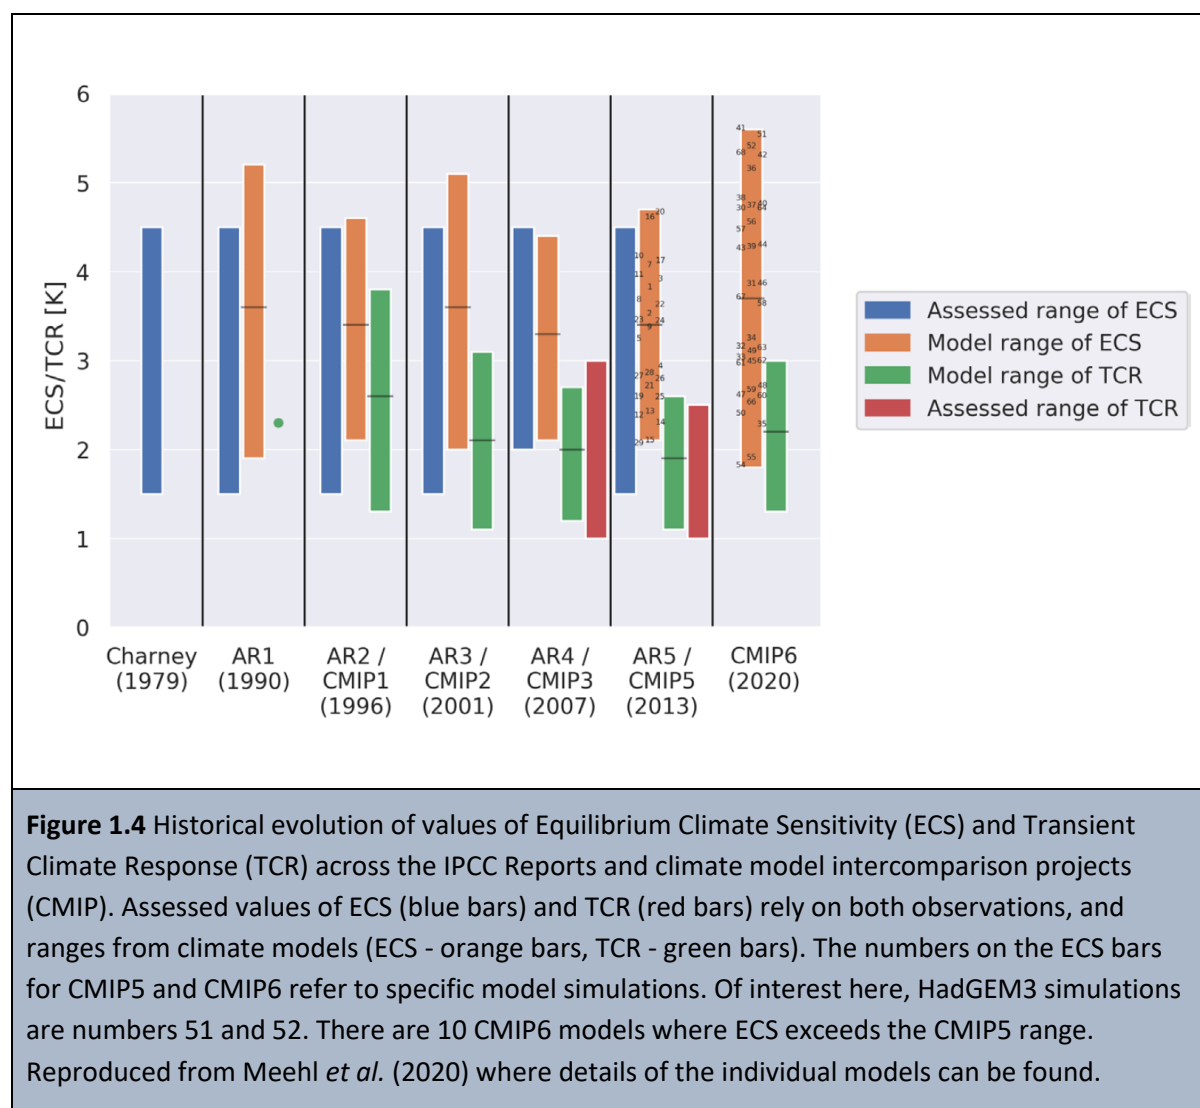

In summary, HadGEM3 has delivered significant improvements in simulating the observed variability of the North Atlantic Jetstream in terms of both its latitudinal position and the temporal frequency of each preferred location. This means that UKCP18 results based on HadGEM3 are likely to provide a more reliable evidence base for changes in the UK's weather and climate, many of which will depend on how natural climate variability will change and not just on the overall warming.

### 1.2.3 Climate sensitivity in the new UKCP18 projections

The CMIP5 models already cover a wide range of climate sensitivities. However, the climate sensitivity of new Met Office global model, HadGEM3, submitted to CMIP6 lies outside the upper range of the CMIP 5 models. HadGEM3's Equilibrium Climate Sensitivity (ECS) of 5.4°C from preindustrial levels for a doubling of atmospheric CO<sub>2</sub> concentrations can be compared with an ECS of 4.6°C for the earlier version of the Met Office model used in CMIP5. This is higher than in all climate models from previous generations used in the CMIP3 and CMIP5 intercomparison projects (Figure 1.4), but consistent with a sub-set of other recently developed climate models submitted to CMIP6 (Andrews *et al.*, 2019; Forster *et al.*, 2020; Meehl *et al.*, 2020). The causes of the higher ECS in these new climate models are currently being studied in detail, with cloud feedbacks and cloud-aerosol interactions in models with prognostic aerosol schemes seeming to be playing an important role. Zelinka *et al.* (2020) showed that this increase in ECS was primarily associated with stronger positive cloud feedbacks from decreasing extratropical low cloud coverage and albedo in this sub-set of models compared to the corresponding models in the previous generation.

---

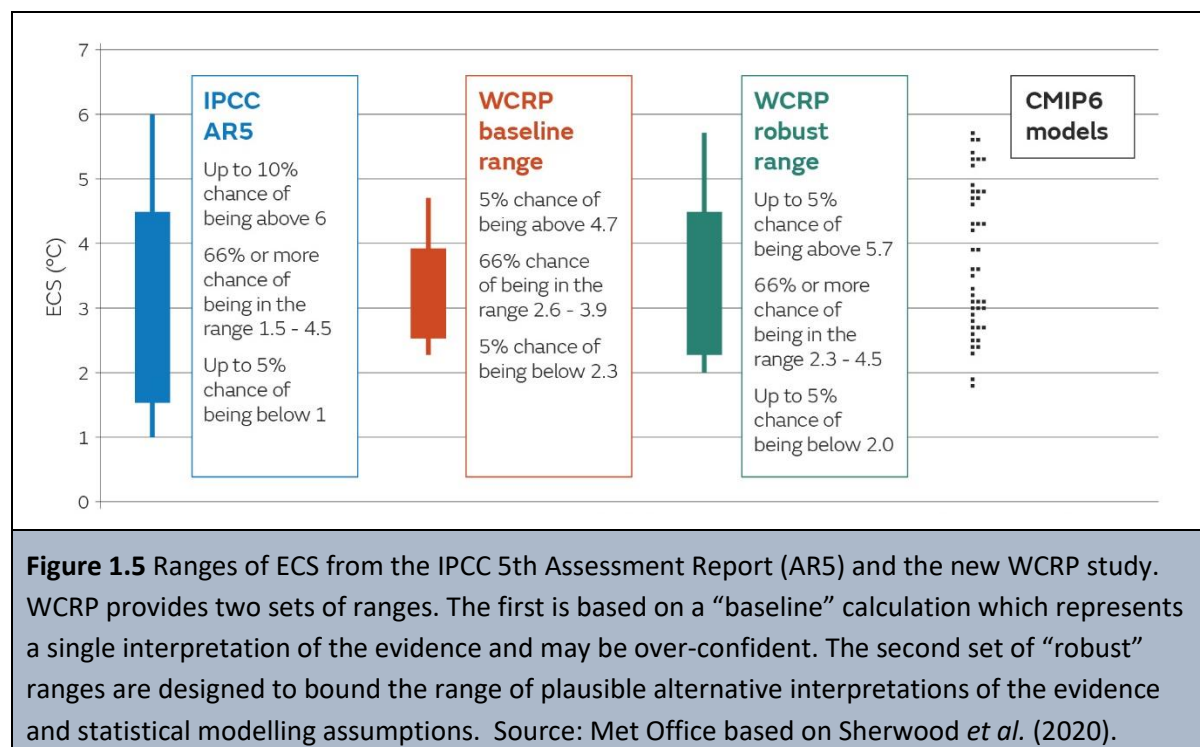

<sup>4</sup> Boundary conditions refer to the time-varying atmospheric conditions that enter the regional model domain and come from the global climate model in which the regional model is embedded. This means that, to a large extent, the regional model is 'slave' to the global model's simulation of weather and climate variability; this is why the choice of global driving model is so important.

As increased climate sensitivity increases projected global warming under future emissions scenarios, establishing the plausibility of these higher sensitivity models is imperative given the potential implications for climate risk assessments. In 2015, the World Climate Research Programme (WCRP) commissioned a major international study to explore whether it is possible to constrain the estimates of ECS using the latest evidence including (i) feedback process understanding, (ii) the historical climate record, and (iii) the paleoclimate record. A summary of the results of this comprehensive study (Sherwood *et al.*, 2020) is shown in Figure 1.5.

The most important result is that it is impossible to reconcile sensitivities less than 2°C from these three strands of evidence; indeed, this new study suggests that the "likely range" (>66% probability range) has narrowed to, at most, 2.3°C to 4.5°C - or possibly an even narrower range of 2.6°C to 3.9°C when all lines of evidence are considered. The lower end of this range is increased substantially from the 1.5°C lower bound in IPCC AR5, meaning that scientists are now much more confident that global warming will not be small.

In addition, according to Sherwood *et al.* (2020), there is up to an 18% chance that ECS is above 4.5°C, but no more than a 5% chance that it is above 5.7°C. So, while HadGEM3 is at the high end of these estimates, its ECS cannot be eliminated by other lines of evidence.

Another way to assess the plausibility of a model’s climate sensitivity is to test its skill in weather forecast mode, as advocated by Rodwell and Palmer (2007). This is not widely attempted because very few climate models are also run as weather forecasting models, with the UK Met Office being unusual in this respect. Williams *et al.* (2020) describe tests of HadGEM3 in weather forecast mode, in which they investigated the validity of the model changes responsible for increasing the climate sensitivity. The results showed that these model changes improved the short-range weather forecast and reduced the error growth over the first few hours of the forecast. This suggests that the physical processes represented by these model changes may be a more accurate representation of the real world, and so it is not possible to dismiss completely the high ECS of HadGEM3 as a plausible possibility.

ECS is an idealized quantity that reflects the very long-term (150 years plus) response of the Earth System to a constant forcing of double CO<sub>2</sub>. Transient Climate Response (TCR; warming at the time of CO<sub>2</sub> doubling in an idealized 1% per year increase in atmospheric concentration scenario) is a better measure of warming over the near- to medium-term and therefore more relevant to climate adaptation.

Figure 1.4 highlights that although the upper end of the ECS has increased substantially in CMIP6 compared to CMIP5, the distribution of TCR has not changed as much. HadGEM3’s TCR (2.6°C) is slightly higher than in some CMIP6 models, but only up from 2.5°C for the corresponding model in CMIP5 (Meehl *et al.*, 2020). Again HadGEM3’s TCR is in the upper part of the CMIP6 range and therefore means a greater rate of global warming compared to that simulated in CMIP5 models,

especially through the latter half of the 21<sup>st</sup> century; this affects the rate of warming at UK scales as well. This indicates that, for the latter half of the 21<sup>st</sup> century, HadGEM3 will generate UK warming at the upper end of the range from previous assessments and will challenge us on how to evolve the risk assessments from CCRA2 to CCRA3.

It would be unwise though, on the basis of this higher sensitivity, to de-emphasise the HadGEM3-related regional and local climate projections from UKCP18. As has already been shown, HadGEM3 is a more skilful model in terms of the mean climate and its variability, especially for the Euro-Atlantic sector and the weather patterns that affect the UK, and consequently may provide a more robust assessment of future changes in high-impact or extreme weather and climate events that are fundamental for UK adaptation and risk assessments. Furthermore, the effects of this high climate sensitivity can be minimised if we consider risks at specific global warming levels rather than time horizons through the 21<sup>st</sup> century. Consequently, we have used both approaches in the following assessment of future climate impact drivers. Generally the HadGEM3 temperature trajectory should be interpreted as a high impact, low probability future but any temperature-level analysis should be considered to be unaffected by climate sensitivity. In this chapter we note when conclusions are affected by the model's high climate sensitivity but generally focus on the robust conclusions that would remain true if the model were to have a lower climate sensitivity.

## 1.3 Climate change that has already occurred

This section summarises the latest evidence that has been accumulated since CCRA2 on the climate change that has been observed across the UK and globally. Each year the Met Office publishes its annual 'State of the UK Climate' (e.g., Kendon *et al.*, 2020), which provides a comprehensive analysis of the latest observational records. Since CCRA2, several UK climate records have been extended further into the past through data archaeology, recovery and digitising of past weather records. UK-wide temperatures now go back to 1880 and rainfall to 1862, both on a 1 km grid (HadUK-Grid; Hollis *et al.*, 2019), and there will be further progress in reconstructing historical weather and climate records for CCRA4. There is also more information on finer timescales (daily and even sub-daily), which is enabling much greater understanding of past extremes.

The UK record can be placed within the context of changes in global and European climate, which are now routinely documented in the annual WMO Statement on the State of the Global Climate (WMO, 2019), the international annual assessments by the American Meteorological Society (Blunden and Arndt 2019) and the European State of the Climate (ESOTC) annual report compiled by the EU Copernicus Climate Change Service (ESOTC, 2019).

### 1.3.1 Temperature and Heatwaves

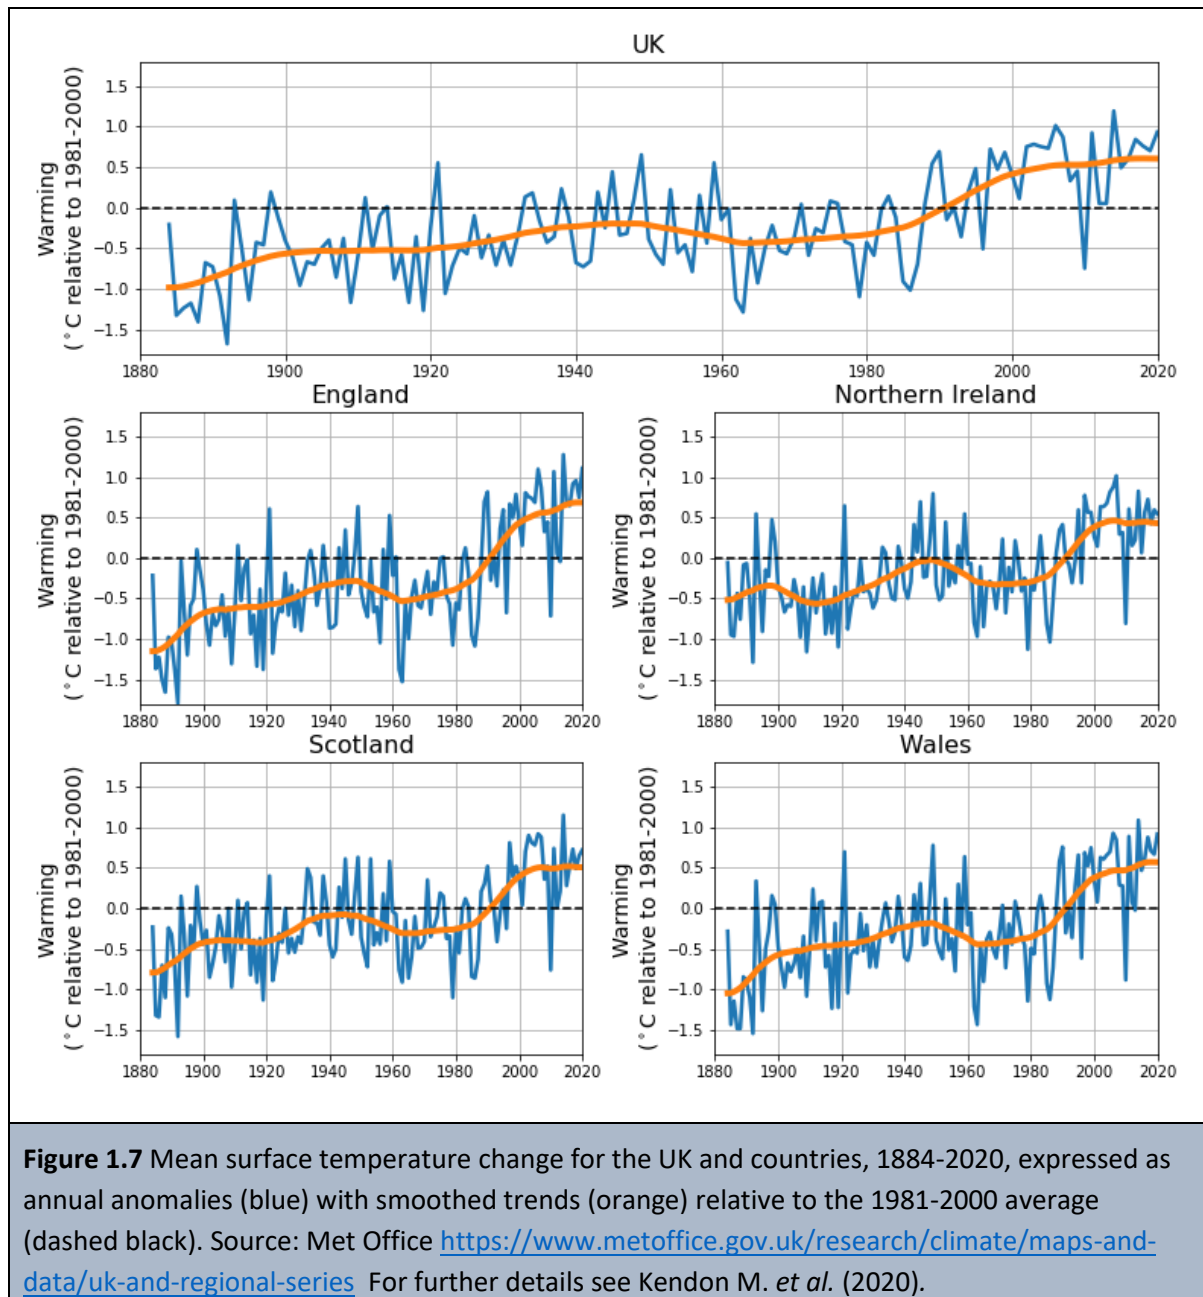

The Earth has continued to warm as measured by the GMST (Figure 1.6), with 2020 the warmest or second warmest year on record. Furthermore 2010 - 2019 concludes the warmest 'cardinal' decade globally (spanning those years ending 0-9) in records that stretch back to the mid-19th century, with the last 6 years being the warmest six years over the whole observed record. Other components of the climate system also show increasing evidence of anthropogenic warming such as declines in

Arctic sea ice and glacier mass, rising sea levels, increases in atmospheric humidity, more warm days and fewer cold days (Blunden and Arndt, 2019).

The same evidence for continued warming is also seen in the UK land temperature record (Figure 1.7), although due to the very cold winter of 2010, the last decade has only been the second warmest of the 'cardinal' decades over the last 100 years of UK weather records, slightly behind the 2000s. Based on the Central England Temperature record (the longest instrumental temperature record in the world), the 21<sup>st</sup> century has so far been warmer overall than any 20-year period in the previous three centuries. Around the UK, coastal waters continue to warm, at rates very similar to UK land temperatures in Figure 1.7. For the most recent decade coastal waters have been 0.3°C warmer than the 1981-2010 average and 0.6°C warmer than the 1961-1990 average.

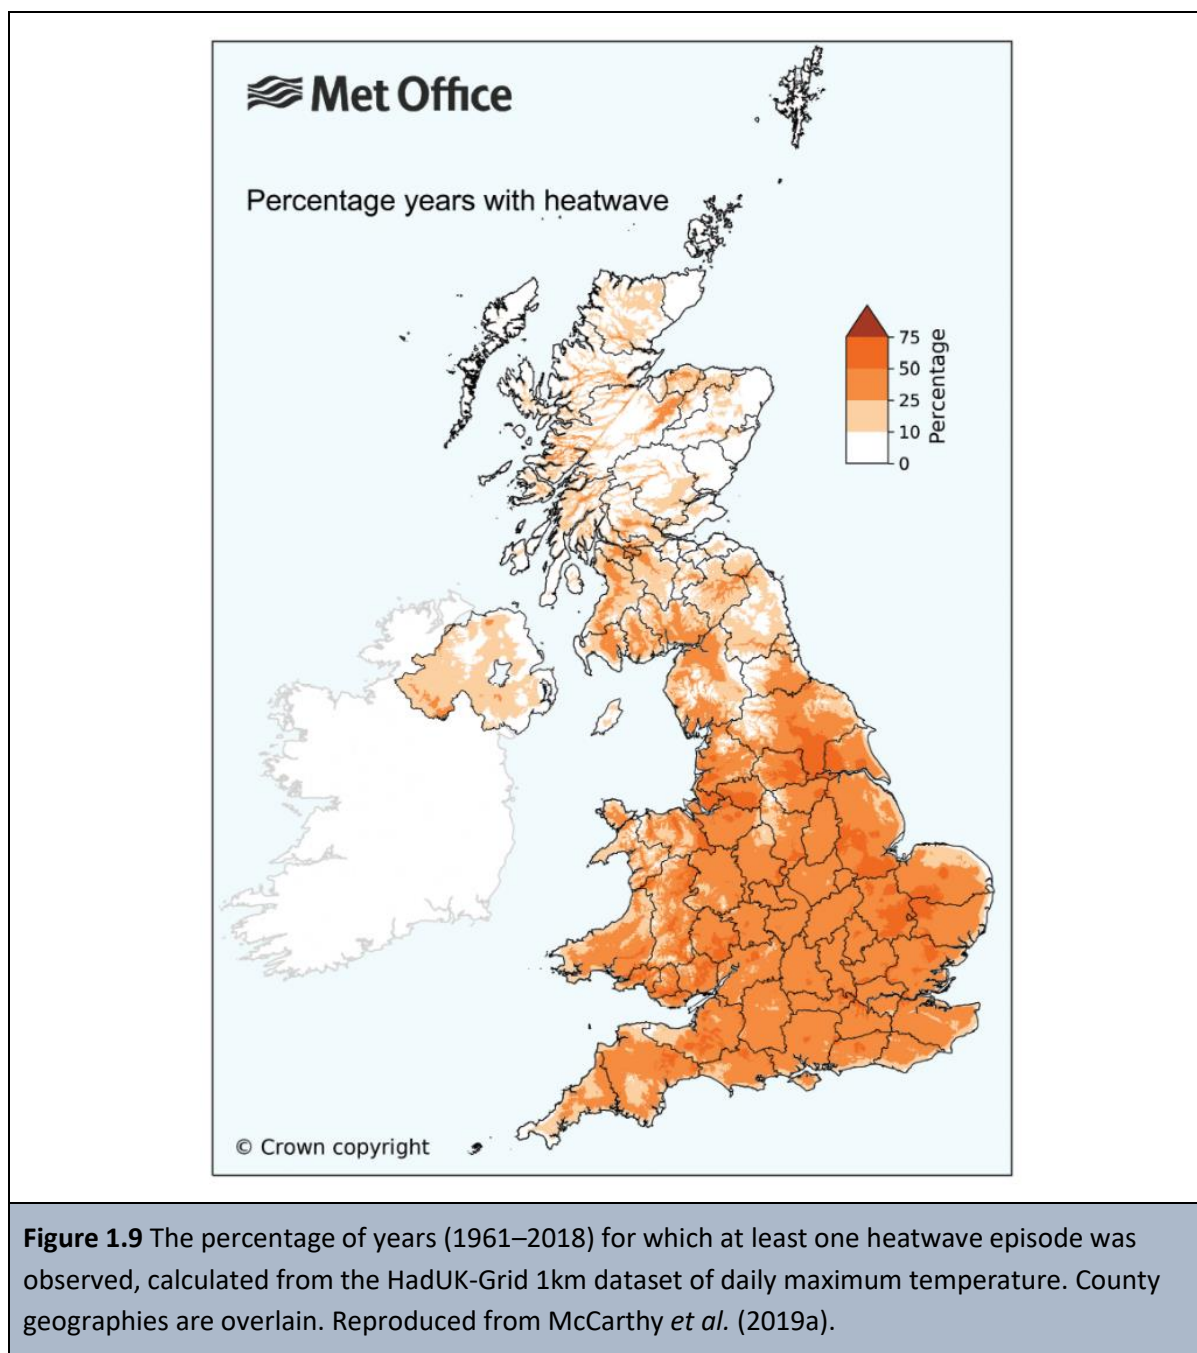

It is also notable how many of the UK's record extreme monthly temperatures have been set in the most recent decade (Figure 1.8), and how many more of them are reflecting high, rather than low, temperature extremes, again a consequence of the UK's warming climate. Furthermore, as reported by Kennedy-Asser *et al.* (2020), UK summer temperature extremes (expressed as the 95<sup>th</sup> percentile) are warming 15-48 % faster than the UK summer mean and >50 % faster than the global mean annual temperature. In July 2019, the UK recorded its highest daily maximum temperature of 38.7°C in Cambridge.

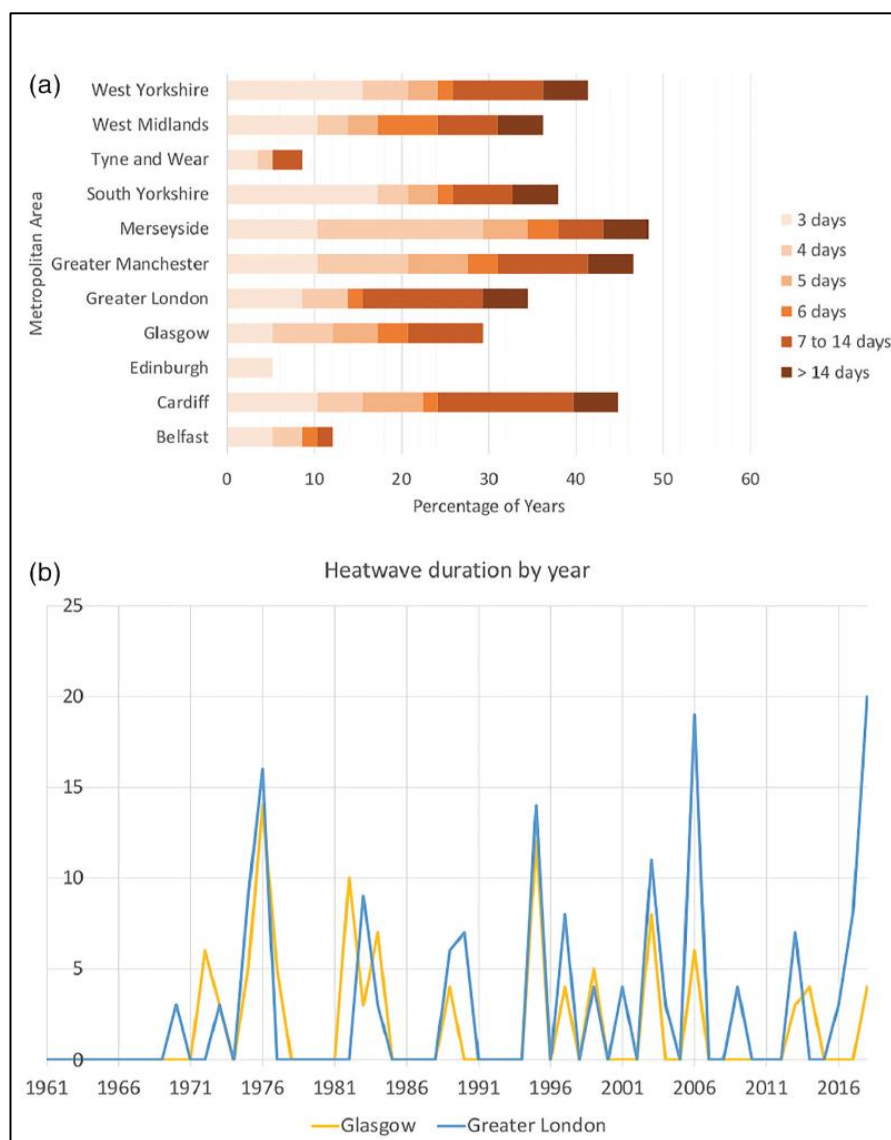

The continuing warming of the UK's climate across all seasons and nations is also reflected in other climate metrics that influence, for example, energy demand and agricultural production, including increases in the number of cooling degree days and growing degree days, and declines in the number of heating days and frost days (Kendon M. *et al.*, 2020).

A recent study of heatwaves (McCarthy *et al.*, 2019a), using the new HadUK-Grid daily dataset (Hollis *et al.*, 2019), provides important information on their spatial and temporal characteristics since 1961. In this case, a heatwave is defined using the new metric described in McCarthy *et al.* (2019a). A UK heatwave is declared when a location records a period of at least three consecutive days with maximum temperatures meeting or exceeding a heatwave temperature threshold, in which the threshold varies by UK county in the range 25–28°C.

Using this new definition, Figure 1.9 shows the frequency of heatwaves across the UK between 1961 and 2018, expressed as the percentage of years in which a heatwave is declared. Across the southern half of the UK, 30–50% of years have experienced at least one heatwave period.

The duration and frequency of individual heatwaves is shown in Figure 1.10(a) for major metropolitan areas of the UK. It shows that durations in excess of 1 week are quite common and those in excess of 2 weeks can account for around 10% of all heatwaves. Figure 1.10(b) shows the timeseries of heatwave duration for the major cities of London and Glasgow. The extreme years of 1976, 1995, 2006 and 2018 are clearly seen, along with a tendency for more heatwaves in London in recent years.

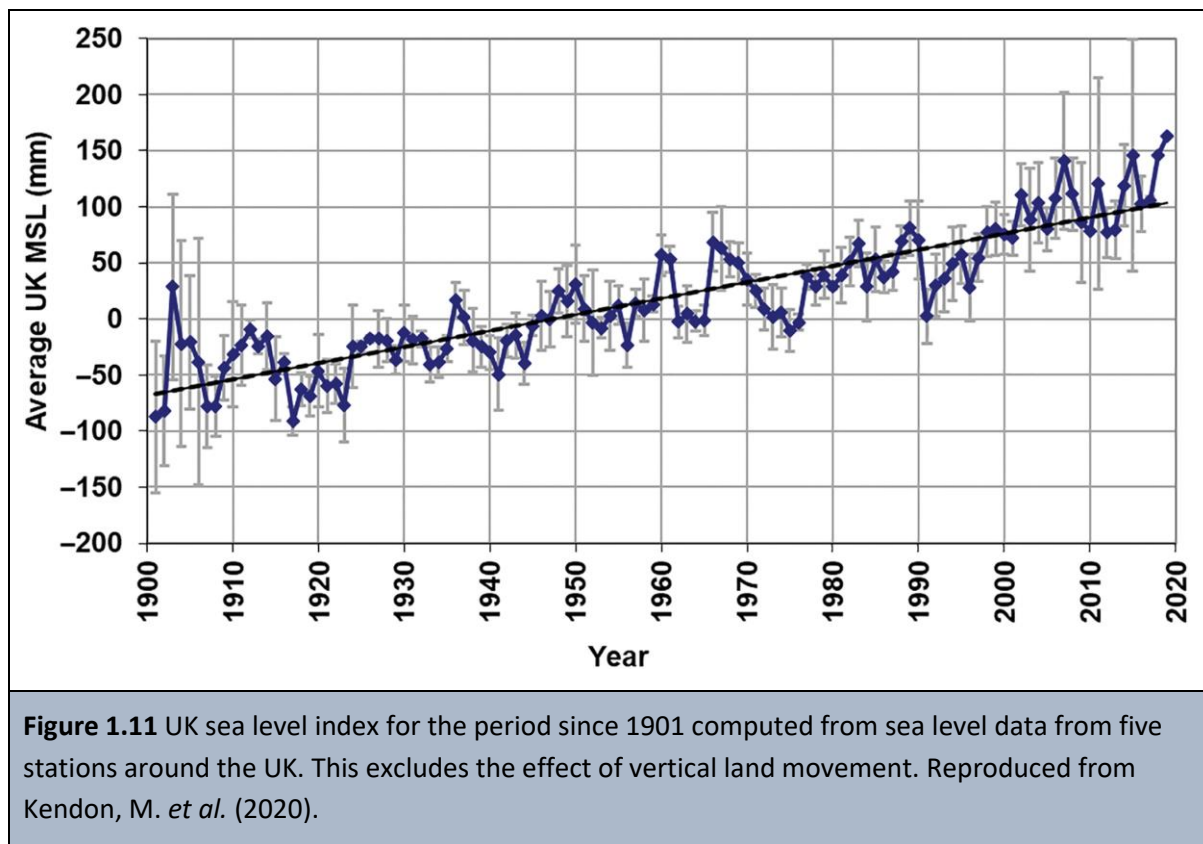

**Figure 1.10** (a) Heatwave duration presented as the proportion of years since 1961 with the listed number of heatwave days by Metropolitan Area. (b) Heatwave duration by year for Glasgow and Greater London. Reproduced from McCarthy *et al.* (2019a).

### 1.3.2 Sea Level Rise

Sea level is an important climatic impact driver for the UK, causing inundation in low-lying coastal areas, exacerbating coastal erosion, increasing tidal locking<sup>5</sup> in some rivers, and making storm surges more damaging. The latest assessments show that sea level continues to rise (Figure 1.11). Since 1901, UK sea level has risen by  $1.4 \pm 0.2\text{mm/year}$  when excluding the effect of vertical land

<sup>5</sup> Tidal locking describes the impact of tides on the ability of rivers to drain out to the sea. In very low-lying areas such as the Somerset Levels, the fall on the rivers may be so small that only during the lowest parts of the tidal cycle is the river able to drain to the sea. This was a major factor in the Somerset floods during the 2013/14 winter. This tidal locking will increase as mean sea level rises.

movement, in line with the global figure of  $1.7 \pm 0.2\text{mm/year}$ . This rise is not uniform around the coast due a number of large-scale atmosphere and ocean processes.

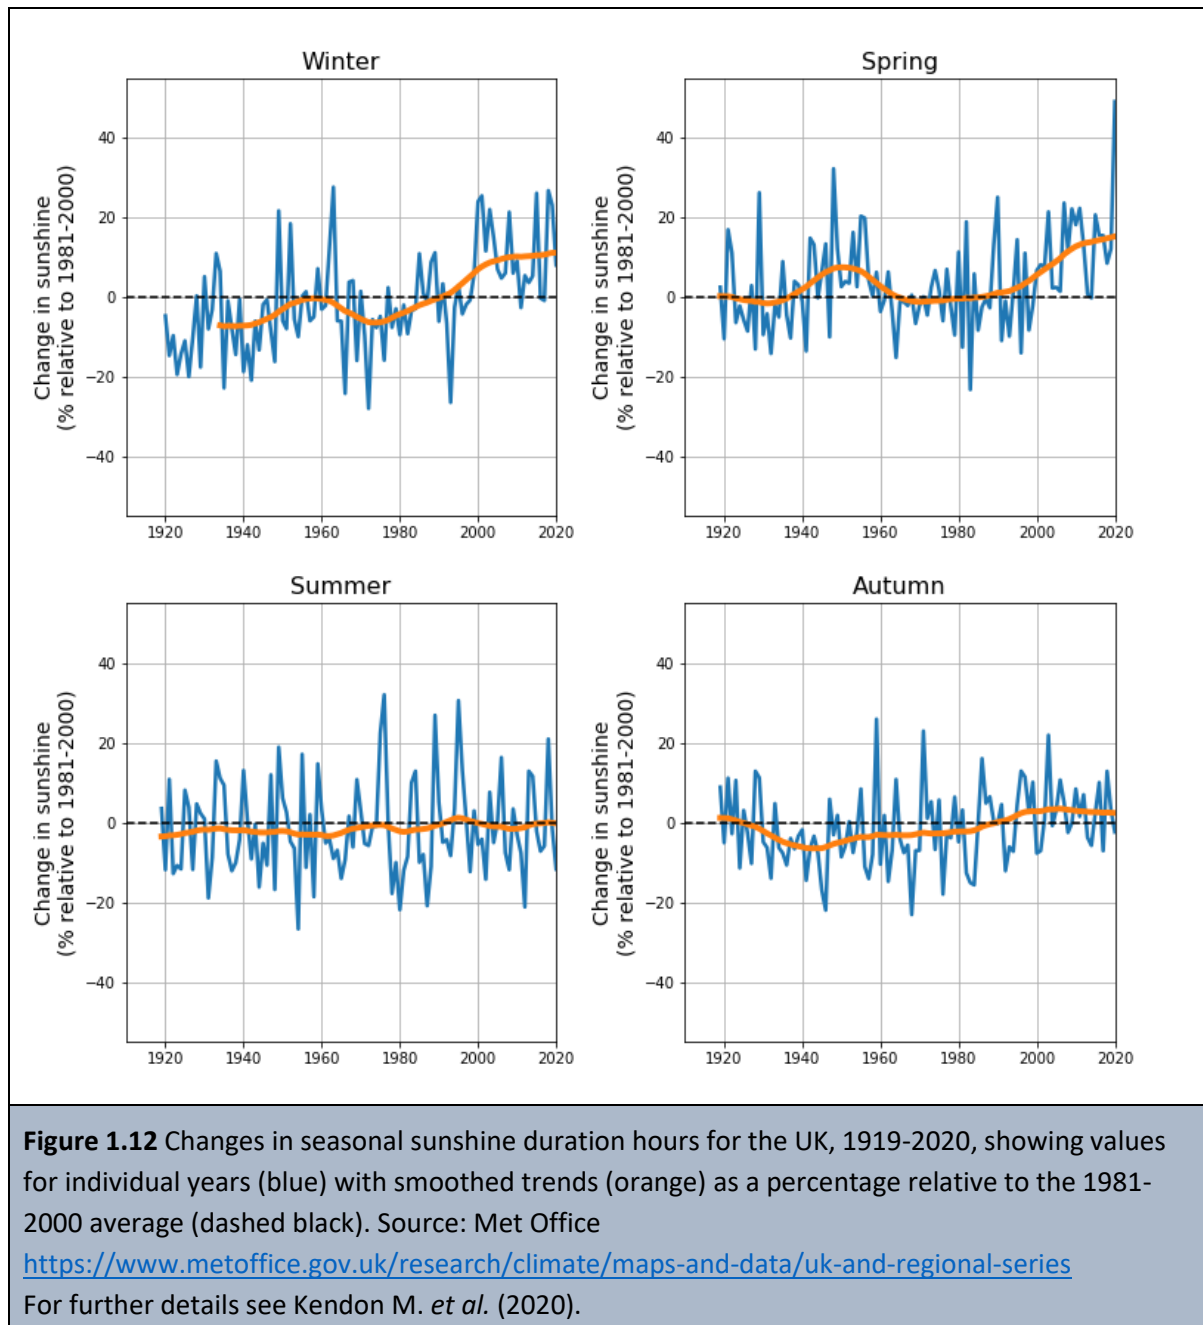

Only a limited number of stations are used to construct the long-term record. A more comprehensive reconstruction by Hogarth *et al.* (2020) for the period 1958–2018, has shown that in recent decades the mean rate of sea level rise may be higher at  $2.39 \pm 0.27 \text{ mm yr}^{-1}$  and that this rate is accelerating by  $0.058 \pm 0.030 \text{ mm yr}^{-2}$ . This is in line with the IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (IPCC SROCC, 2019), which reported that the rate of rise in global mean sea level for 2006–2015 of  $3.6 \text{ mm yr}^{-1}$  is unprecedented over the last century.

### 1.3.3 Sunshine

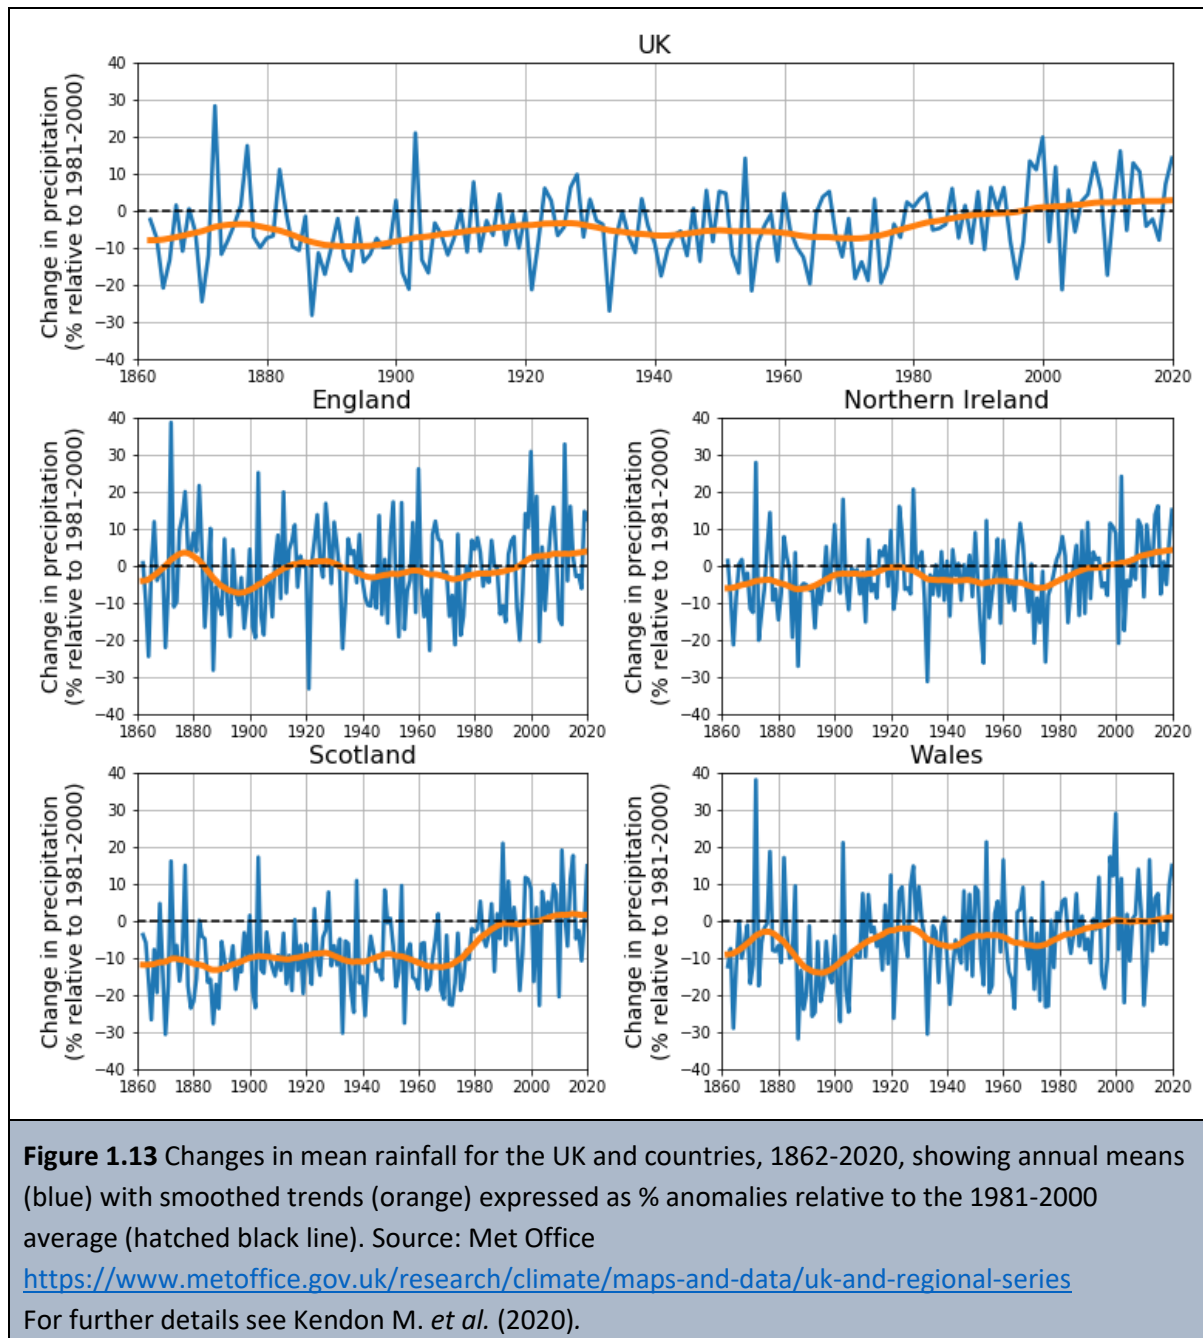

Temperature and sea level rise provide the most compelling evidence of a changing climate for the UK; changes in other weather and climate metrics are more difficult to detect due to their inherent large natural variability. However, a clear trend is emerging for increasing sunshine hours for all parts of the UK and especially during winter and spring, where the most recent decade has been higher by 11% and 16% respectively, compared with 1961–1990 (Figure 1.12). The run of sunny springs in recent years is particularly notable, with 2020 being the sunniest spring on record for all UK countries in series stretching back to 1929.

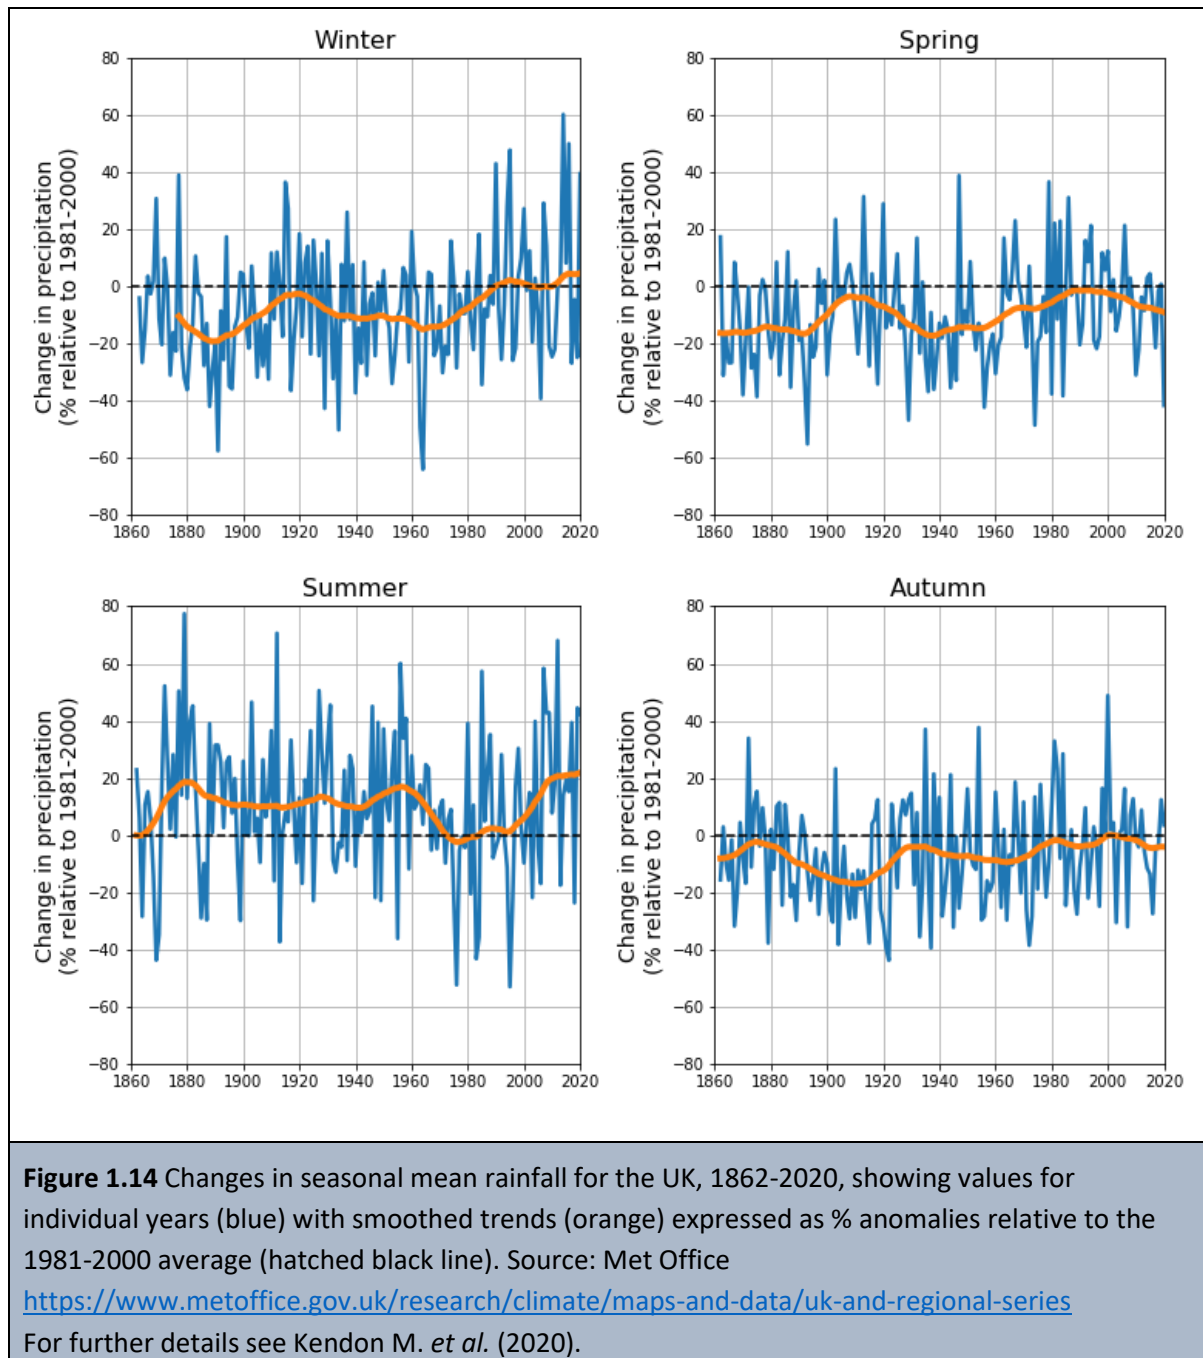

### 1.3.4 Mean Rainfall

Annual mean rainfall (Figure 1.13) is dominated by natural variations, although there are indications of small increases over the UK and its nations since the 1970s, especially for Scotland.

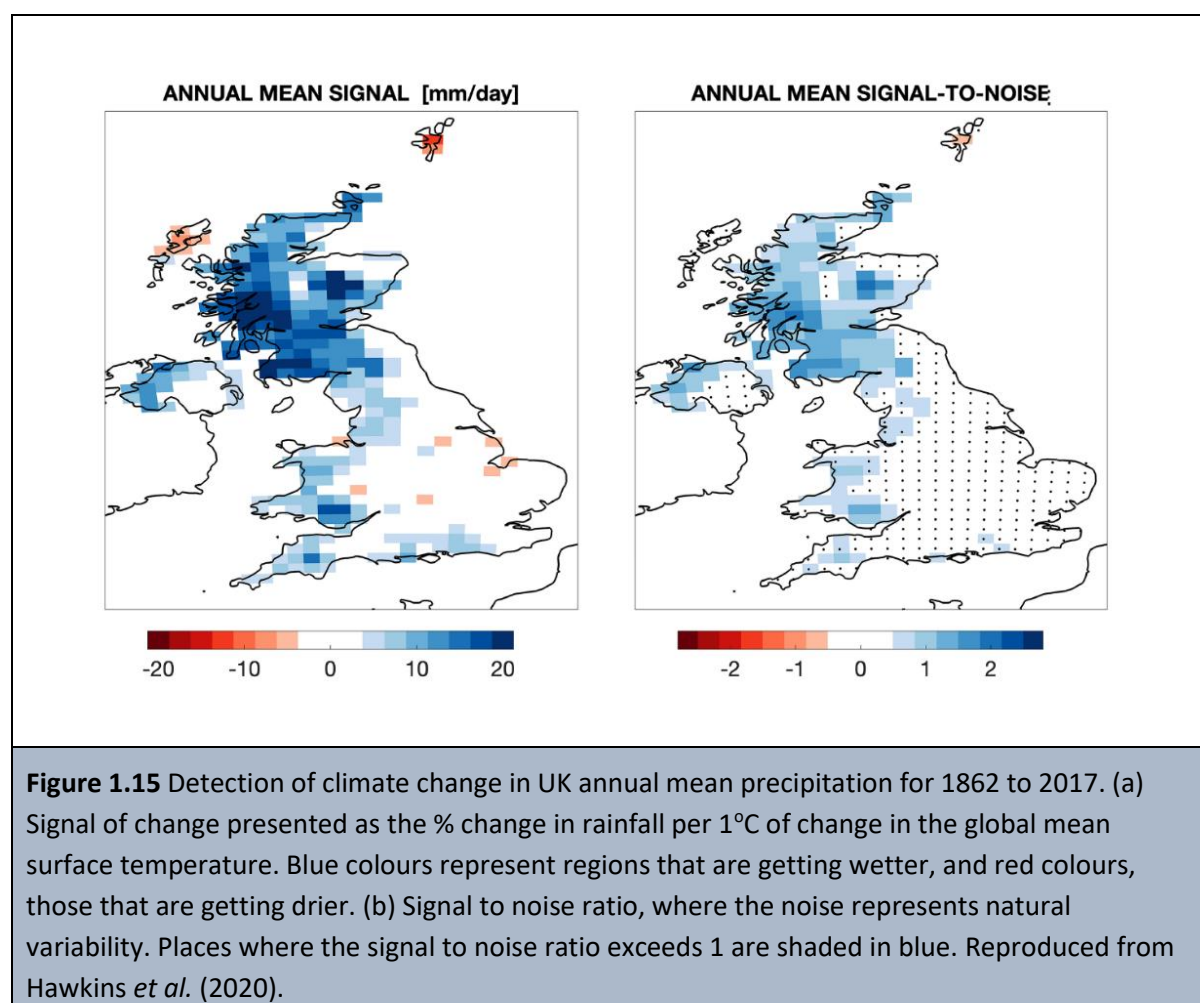

Seasonal UK rainfall has always been dominated by interannual and decadal variability (Figure 1.14). There is some evidence of increased winter rainfall in recent decades and some notable extremes (winter 2014 is the wettest winter in this series and 2016 ranked eighth wettest). Any trend towards drier summers is less evident, with a recent spell of wet summers between 2007 and 2012.

For many impacts requiring adaptation, it is the amplitude of the change relative to the local amplitude of climate variability which is more relevant. A new analysis of the UK rainfall data for 1862-2017 by Hawkins *et al.* (2020) has recently shed some light on the detection of climate change in rainfall using the HadUK-Grid dataset. By expressing the signal (S) as the % change in rainfall per 1°C change in the global mean surface temperature, they were able to detect regional variations in rainfall trends associated with global warming across the UK (Figure 1.15). When that trend is removed from the timeseries, the remaining noise (N) due to natural variability can be quantified and the ratio between signal and noise indicates if and where the effects of climate change are beginning to emerge from natural variability.

Figure 1.15(a) shows that the signal (S) for trends in annual mean rainfall associated with global warming is dominated by increases, mainly over the west side of the UK and especially over Scotland. Hawkins *et al.* (2020) further showed where the signal exceeded the noise (S/N), identifying Scotland and the mountainous regions of western England (Figure 1.15(b)). Where S/N exceeds 1, this can be interpreted as places where the climate is now moving from the ‘familiar’ towards being ‘unusual’, relative to lived experience, using the terminology as defined by Frame *et al.* (2017).

In all regions, the influence of climate change is to increase rainfall, consistent with fundamental physics that says that warmer air holds more moisture (i.e., for 1°C rise in temperature, atmospheric moisture content – and by inference regional rainfall - increases by 7%). Figure 1.15(b) clearly identifies Scotland and the mountainous regions of western England where S/N exceeds 1 and therefore where the influence of climate change is already emerging and potentially challenging our resilience.

### 1.3.5 Rainfall extremes

While robust evidence for trends in the UK's annual and seasonal rainfall is emerging year on year, we need also to consider whether the same is true for extreme rainfall which can be particularly damaging.

There is a growing body of literature (e.g., Guerreiro *et al.*, 2018) which argues that the effects of global warming on the hydrological cycle are being manifested in changes in the frequency and intensity distributions of daily and sub-daily rainfall, even when averages over longer timescales are stable.

There is some evidence for the increasing occurrence of widespread heavy daily rainfall across the UK in the last few decades (Figure 1.16), such as autumn 2000 and winter 2013/14. Although the record is too short to be conclusive, this is in line with fundamental physics that says that warmer air holds more moisture. In other words, a weather system today would give more rainfall than the same system in 1950. The statistics on local extreme daily rainfall (Figure 1.16), based on individual station records, also suggest an increasing occurrence, although the gauge network is not ideally suited to detect localized events.

In a major review of the latest evidence on the current anthropogenic intensification of short-duration rainfall extremes, Fowler *et al.* (2020) conclude that:

- Heavy rainfall extremes are intensifying with warming at a rate generally consistent with the increase in atmospheric moisture (i.e., 7% per °C), for accumulation periods from hours to days.
- In some regions, stronger increases in short-duration, sub-daily, extreme rainfall intensities have been identified, up to twice what would be expected from atmospheric moisture increases alone.
- Stronger local increases in short-duration extreme rainfall intensities are related to convective cloud feedbacks involving local storm dynamics.
- The evidence is unclear whether storm size has increased or decreased with warming; however, increases in rainfall intensity and the spatial footprint of the storm can compound to give significant increases in the total rainfall during an event.
- Evidence is emerging that sub-daily rainfall intensification is related to an intensification of local flash flooding. This will have serious implications for flood risk management and requires urgent climate-change adaptation measures.

### 1.3.6 Storminess and winds

Storms are an important climatic impact driver for the UK and there has been considerable debate on whether storminess is increasing, particularly after the 2013/14 winter, which was the stormiest

winter for at least 143 years when cyclone frequency and intensity are considered together (Matthews *et al.* 2014).

A comprehensive review of the evidence has been presented by Feser *et al.* (2015) who concluded that there is as yet no clear evidence for increased storminess. This was confirmed by a more recent study by Krueger *et al.* (2019). Both studies showed that trends in storm activity depend critically on the time period analysed, and that the apparent increase in storminess between 1960 and 1990 is actually part of a longer-term record that reveals multi-decadal variability. In other words, large-scale natural climate variability, such as the North Atlantic Oscillation, dominates the intensity and frequency of UK storms.

Kendon M. *et al.* (2020) confirmed this result when they analysed strong wind gusts across the UK (Figure 1.17), which showed increases in wind gusts over 40 knots in the latter part of the 20<sup>th</sup> century and a decline thereafter. Nevertheless, more research is needed to address this important question for the UK, since major storms can cause widespread damage, from flooding, winds and waves to coastal storm surges.

### 1.3.7 Summary

The latest observations show that the UK continues to warm, sea levels continue to rise, and an increasing number of climatic impact drivers are beginning to show clearer evidence of a changing

climate. Beyond the mean climate there is a growing body of evidence for changes in the frequency and/or intensity of high-impact weather events, such as extreme daily rainfall and heatwaves. New records are being set more frequently, with the UK experiencing unprecedented high temperatures and heavy rainfall. However, the evidence base for changes in storminess is weak and this needs to be addressed with some urgency. The next section will provide the latest evidence on how to interpret these events and the extent to which they can be attributed to climate change.

## 1.4 Interpreting the observational evidence on extremes

The previous section has identified a number of climatic impact drivers where climate change can be detected, in other words the observations lie outside the envelope of natural variability. The next question is whether those changes can be attributed to anthropogenic forcing or whether they are due to other drivers such as multi-decadal variability. We are now confident that the trends in UK average surface temperature can be attributed to anthropogenic global warming, but other climatic impact drivers, especially related to precipitation are still challenging.

We know that extreme weather and climate events can be very costly, and it is increasingly important to know whether human influences are affecting their severity and frequency so that we can plan accordingly. Knowing the relative contribution of climate change to these events allows us to assess how our risk envelope is changing and what our near-term adaptive responses should be.

Since CCRA2, the science of extreme event attribution has continued to develop (e.g., Stott *et al.*, 2016, Vautard *et al.*, 2019), including progress towards an operational attribution service (e.g., <https://www.worldweatherattribution.org>). There are two possible approaches to attribution of extremes. The first is framed around the probabilities of such an event occurring in a world with and without raised concentrations of greenhouse gases due to human activity. It relies on model simulations and is therefore dependent on the skill of the model in capturing these extreme events (e.g., Stott *et al.*, 2004). The second approach is framed around a storyline, which examines the role of the various factors contributing to a specific event as it unfolded, including the anomalous aspects of the meteorology. By analyzing the contribution of the particular weather pattern to the event, it is possible to isolate the potential contribution from climate change.

A good example of these two approaches is seen in the recent analysis of the causes of the UK summer 2018 heatwave (McCarthy *et al.*, 2019b). Based on the probabilistic approach using an ensemble of global climate simulations, they concluded that climate change had increased the likelihood of the summer 2018 heatwave by a factor of 30, assuming of course that the simulations are able to represent the weather patterns that give rise to UK heatwaves with some fidelity.

However, these estimates do not include the specific context of each heatwave and we know that each one is set up differently and framing the question around an event-based storyline approach, enables this to be addressed. McCarthy *et al.* (2019b) showed that most of the high temperature anomalies during the summer 2018 heatwave can be explained by the prevailing circulation anomalies - in particular, a strongly positive summer NAO that raised the sea surface temperatures of UK coastal waters, as well as by other feedbacks, such as the extremely low levels of soil moisture following an extended dry spell during early summer. Importantly, though, McCarthy *et al.* also note that these factors alone are not sufficient to explain the intensity of the heatwave, which also has an underlying cause related to the warming UK climate.

This study emphasises the importance of understanding whether the specific circulation patterns that give rise to extreme events will become more prevalent or not under climate change. Other studies of recent extremes have shown, for example, that the extremely cold start to the spring of 2018 is much less likely under global warming, although the circulation pattern that gave rise to it may be slightly more likely (Christidis and Stott, 2020).

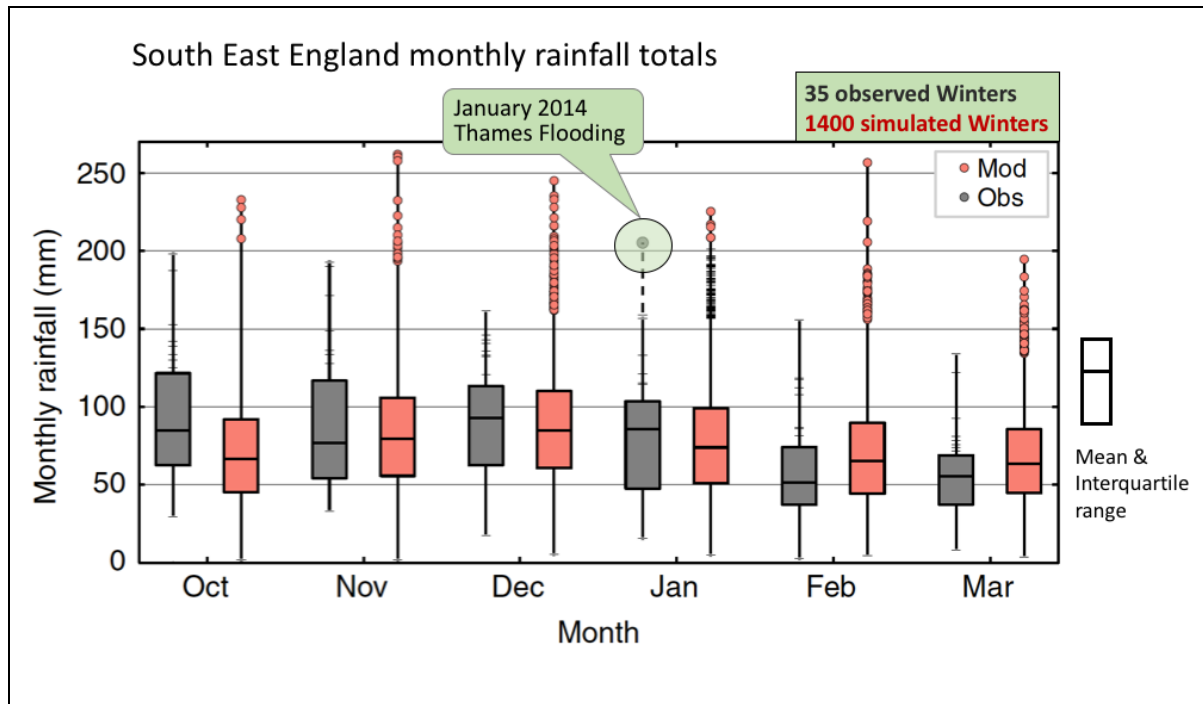

The Doncaster Floods of Autumn 2019 have yet to be formally attributed to climate change. The summer and autumn were exceptionally wet and with the jet stream positioned anomalously to the south in October, a series of cyclonic systems brought prolonged and persistent rainfall on top of already saturated soils. Likewise, the severe Welsh and Severn floods of February 2020 were preceded by a very wet winter, with the compounding effects of a series of storms, none of which were exceptional. As with the widespread flooding that occurred in 2013/14 and again in 2015/16, the prevailing weather patterns clearly played the key role (e.g., Christidis and Stott, 2015). Nevertheless, the extreme rainfall totals and the severity of the flooding are consistent with the basic premise that a warming world holds more moisture; in other words, the same weather system 50 years ago would have produced less rainfall than today.

One of the issues in understanding extremes for the recent past and present day is that the observational record does not necessarily capture the full range of possible outcomes for extreme weather in a particular location, even under the current climate, simply because such events are by definition rare. For the UK, this is particularly challenging. The natural volatility of our weather means that the observational record is far too short to characterise extreme events with confidence and provide robust estimates of return periods. At the same time the statistics of observational extremes are non-stationary (i.e., they vary with time) due to low frequency, multi-decadal natural variability and the emerging effects of anthropogenic climate change. Empirical methods for analysing extremes based on the limited observational record, tend to assume stationarity and potentially have limitations.

Since CCRA2, weather and climate models have been increasing in the level of skill and granularity. They are now able to provide exciting opportunities to use model simulations to produce large sets of synthetic but meteorologically plausible extreme weather events (orders of magnitude larger than observational records) for the current (and future) climate; in other words, pseudo-observations that act to fill out the extreme ends of the observed distribution. They enable return periods (e.g., 1 in 100 years) to be estimated more robustly than using empirical methods based on the short observational record, provided of course that it can be shown that the model can represent, statistically, the real world (Thompson *et al.*, 2017). Consequently, they may serve to provide an improved baseline understanding of current likelihood of extreme weather events, which is valuable in and for itself; it informs planning today, strengthening resilience, as well as providing a reference against which to assess future changes. Synthetic event sets can also be used to explore correlated extremes (such as simultaneous bread-basket crop failures e.g., Kent *et al.*, 2017) and clustering of extremes (such as European windstorms e.g., Priestley *et al.*, 2018).

This methodology, known as UNSEEN (UNprecedented Simulation of Extremes with Ensembles) was first introduced in the Government's National Flood Resilience Review (2016) following the severe flooding during the 2015/16 winter and published by Thompson *et al.* (2017). Figure 1.18 gives an example of the simulated and observed events sets for monthly precipitation in South East England; it shows that by sampling many more meteorologically plausible conditions, a large number of

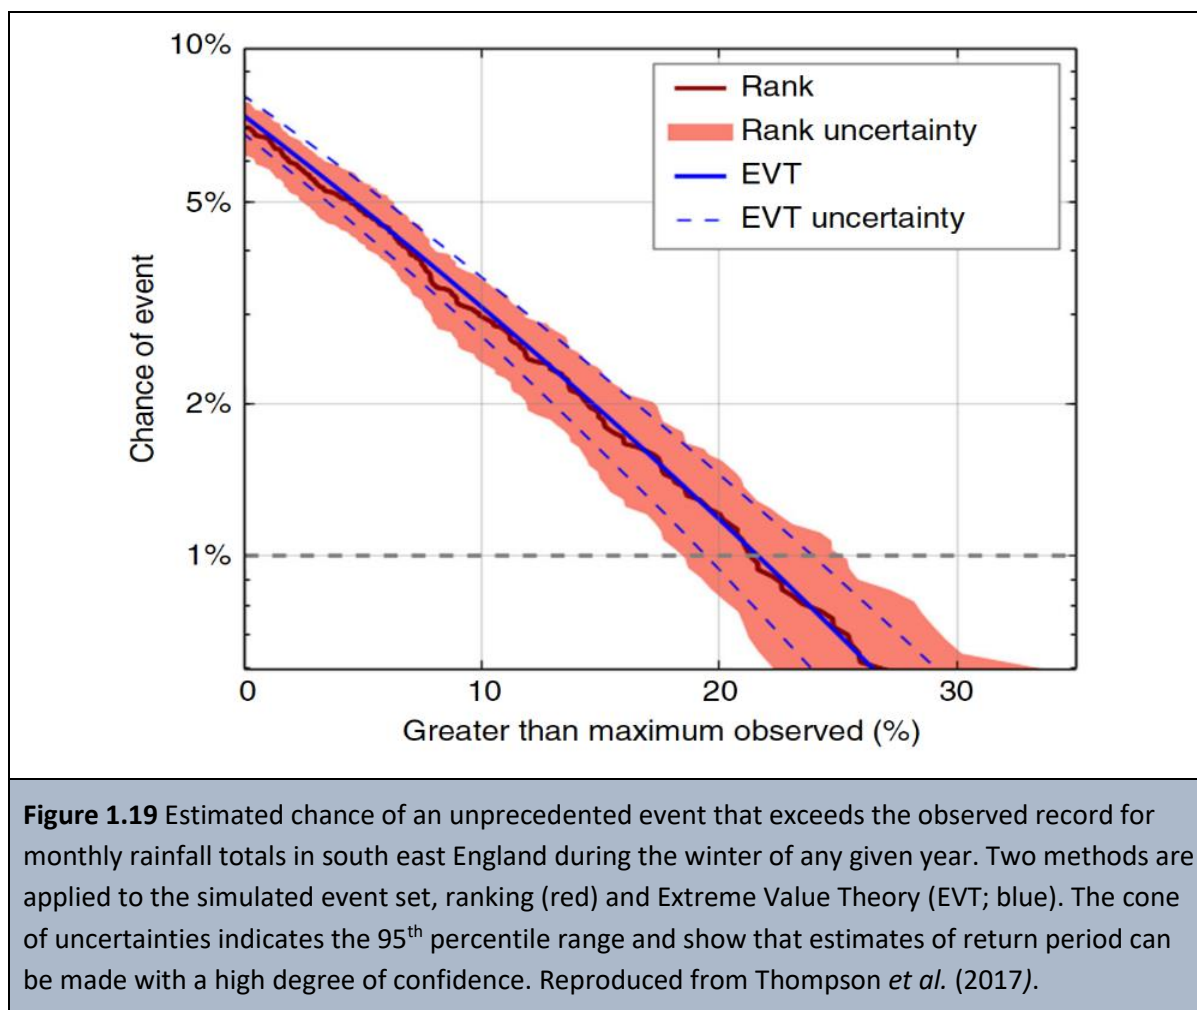

unprecedented extremes can be identified, due to the natural volatility of weather systems. For example, it suggests that the severity of flooding of the Thames in 2014 should not be unexpected, even under present climate conditions, with even more extreme monthly rainfall totals possible.

**Figure 1.18** Example of a climate model-generated, synthetic event set for monthly rainfall for the current climate (red) versus observations (grey), showing that by sampling many more meteorologically plausible conditions, a large number of unprecedented extremes can be found given by the red circles. The median and spread of the simulated and observed events is shown by the box and whisker plots which demonstrate that the simulation event set does not differ statistically from the observations. Reproduced from Thompson *et al.* (2017)

The size of these simulated event sets is many times larger than observations alone and allows exceedance probabilities to be calculated with much more confidence. For example, it can be concluded from Figure 1.19 that currently, in any year, there is a 10% chance of an unprecedented month's rainfall, and that furthermore, there is a 1% risk of receiving 20-30% more rainfall than ever observed before, just from natural variability within today's climate.

The UNSEEN methodology has also been applied to other extremes, such as UK summer heat waves. McCarthy *et al.* (2019b) considered the 2018 event in which summer average temperatures were close to +2°C above the 1981–2010 average for a large swathe of southern and central England and Wales. Using a simulated event set of 4720 samples, McCarthy *et al.* (2019b) showed that there is an 11% chance in any current year of summer temperatures exceeding those in 2018, and a 1% chance that temperatures anomalies may exceed 1°C or more above the 2018 values.

UNSEEN complements future projections from UKCP18 by providing a valuable new tool for assessing current and near-term climate risks by providing better estimates of the tails of the observed distribution for the current climate and providing bounds on what is meteorologically plausible in terms of extreme events. However, like the attribution studies documented above, UNSEEN relies on the model’s ability to represent accurately the statistics of the real world as far as that is possible from the limited observational record, and so detailed evaluation of the model is an essential first step.

In summary, it is now possible to attribute some changes in UK weather extremes to climate change, and significant progress has continued to be made in the attribution of extreme weather events since CCRA2. The science remains challenging because of the UK’s highly variable weather and the fact that these events are, by definition, rare. New research has emphasised the importance of understanding the meteorological context of each individual event, such as the prevailing weather

patterns and the antecedent conditions, as well as recognising that unprecedented extremes will continue to occur just because of natural variability. It remains the case that recent extremes can be largely explained by the prevailing atmospheric circulation anomalies; however, these circulation changes alone are not necessarily sufficient to explain the intensity of the event, which may also have an underlying contribution from the warming UK climate.

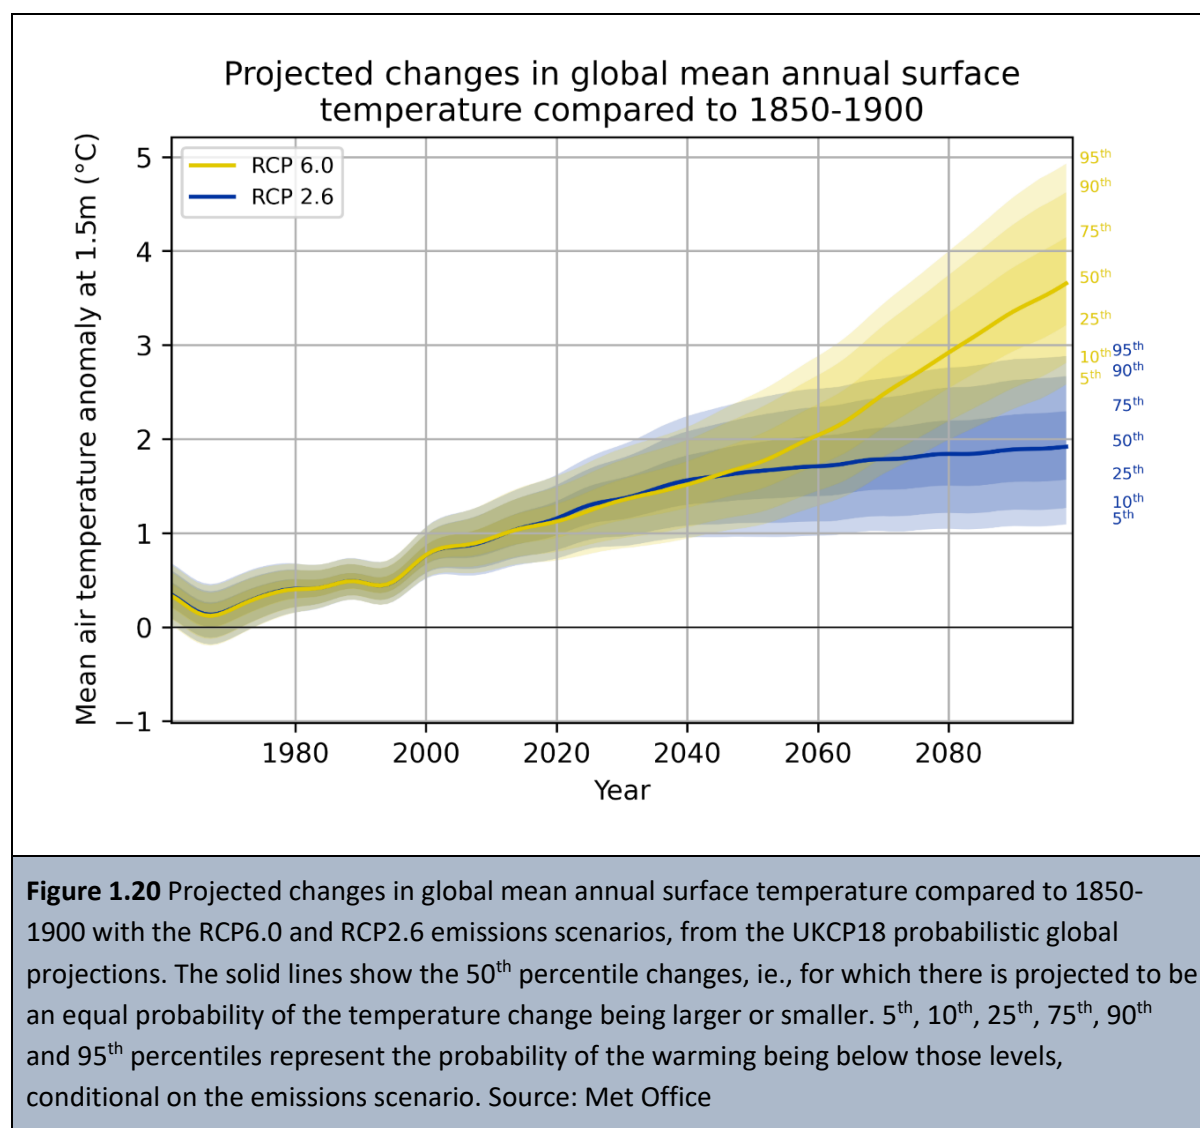

## 1.5 Future Climate Change

This Section draws on the latest UK Climate Projections – UKCP18 – which provide the most up-to-date and comprehensive assessment of future climatic impact drivers for the UK, along with projections of global climate change consistent with the UK projections. It will highlight key differences from the evidence base used in CCRA2 where appropriate. Studies using other climate projections were also used in CCRA3, in addition to information based on UKCP18 – further details on the integration of information from different sources are given in Chapter 2.

### 1.5.1 Projected future global warming

Future changes in global average temperature will depend on future human-caused emissions of greenhouse gases and on the response of the global climate system to these emissions (see Chapter 0). Any particular pathway of future global warming could therefore arise from a number of different combinations of future emissions and climate system responses.

UKCP18 provides global probabilistic projections of the percentage likelihood of different levels of global average temperature change resulting from four emissions scenarios. Two of these – the RCP2.6 and RCP6.0 emissions scenarios – are broadly representative of the pathways to approximately 2°C and 4°C above preindustrial levels by 2100, as used here in CCRA3 to frame the risk assessment (see Introduction Chapter: Betts and Brown, 2021). As Figure 1.20 shows, with the RCP6.0 emissions scenario, the projections give approximately a 30% probability of global warming exceeding 4°C, relative to 1850-1900 (an approximation of the climatic conditions of preindustrial levels) by 2100; with the RCP2.6 emissions scenario, there is slightly more than a 50% probability of global warming at 2100 being below 2°C, relative to 1850-1900. These probabilities reflect uncertainties in both transient climate response and the strength of carbon cycle feedbacks. Importantly, the probabilistic projections are not based on the high-sensitivity model HadGEM3 - they are built from perturbed-parameter ensembles of the HadCM3 model (as used in UKCP09), and also include information from the CMIP5 multi-model ensemble.

UKCP18 also includes projections with the high-end RCP8.5 scenario, especially for the regional and local projections (see Section 1.2.1). Some of these simulations project warming below the 95<sup>th</sup> percentile of that projected with the RCP6.0 emissions scenario, but most are above that. UKCP18 further includes projections with the RCP4.5 emissions scenario; this gives warming that overlaps the lower and upper parts of the ranges with RCP6.0 and RCP2.6 emissions respectively. Further information on this, and comparison with other global warming projections including those used in the UKCP09 projections, and the CMIP5 projections used in the IPCC 5<sup>th</sup> Assessment Report, is given in Annex 1.

### 1.5.2 Projected changes in the UK's annual and seasonal average climate

UK climate change depends on emissions scenarios and global-scale climate responses, and also on the nature of regional climate responses to the global-scale forcing. Overall, the UK is projected to experience ongoing increases in temperature until the middle of the 21<sup>st</sup> Century under all scenarios examined by UKCP18, including RCP2.6. Until that point, the magnitude of regional climate change

depends more on the regional climate responses to a given amount of global average warming, than the difference between the emissions scenarios (Figure 1.21).

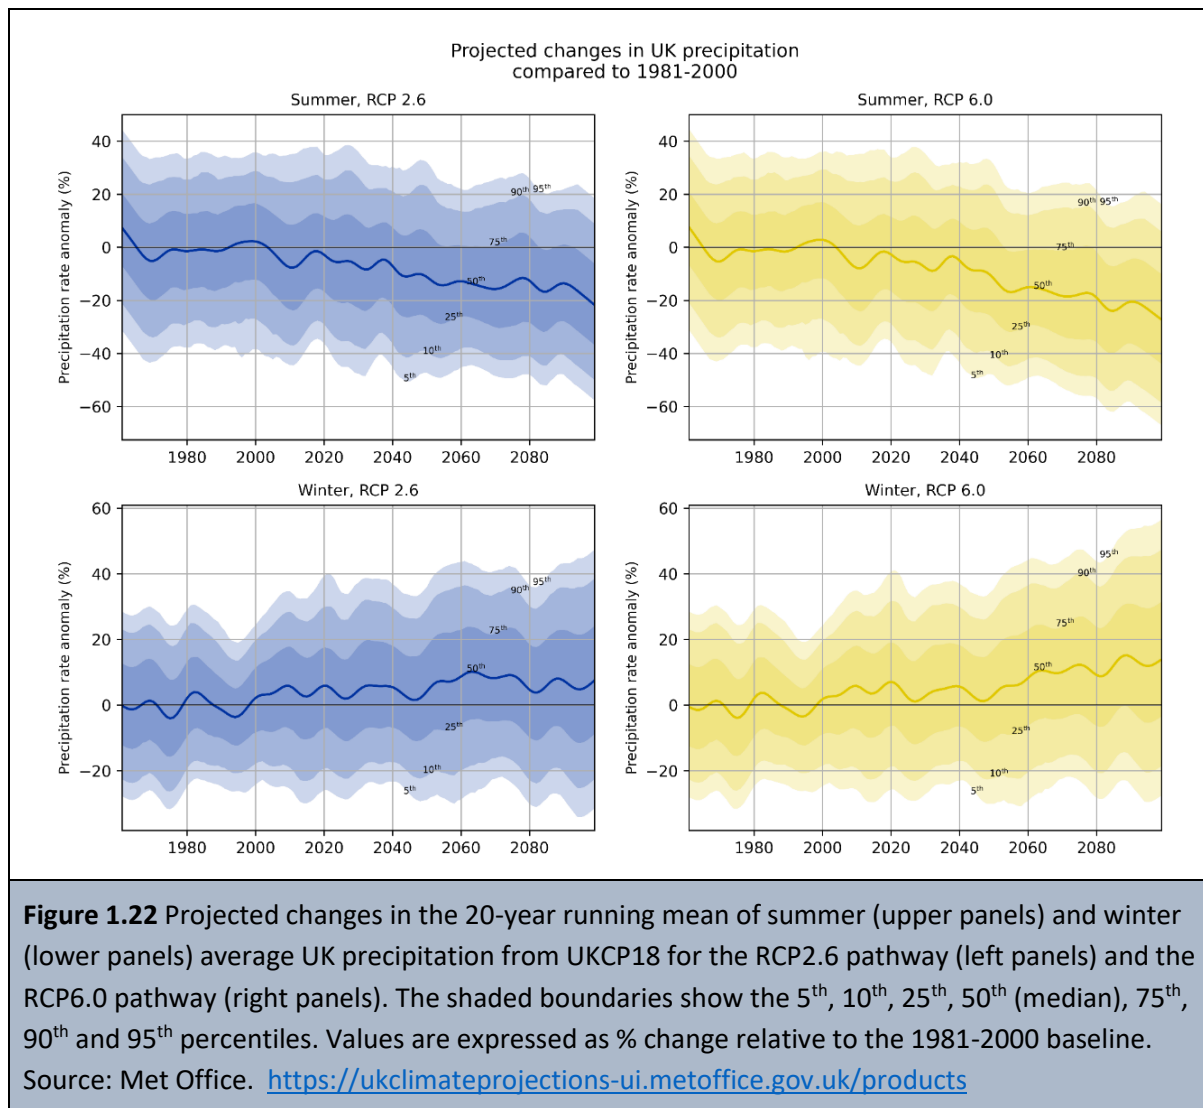

Beyond mid-century, the magnitude of UK climate change depends on the path of future emissions as well as on the regional and global climate response (Figure 1.21). The spread in the projected temperatures by 2100 is larger for RCP6.0 than RCP2.6 and reflects, in part, the increasing contribution to uncertainty from carbon cycle feedbacks, which come into play more substantially in the latter half of the century and at higher temperatures. The warming experienced in the UK is projected to be greater in the summer than the winter (Murphy et al., 2018).

As in earlier assessments there are significant differences in the precipitation signal between winter and summer (Figure 1.22). Even for the RCP2.6 pathway, winters are projected to become wetter overall, whereas summers are expected to become drier. The spread of probabilities is broader in summer than winter, although the difference between the two scenarios is small throughout the century.

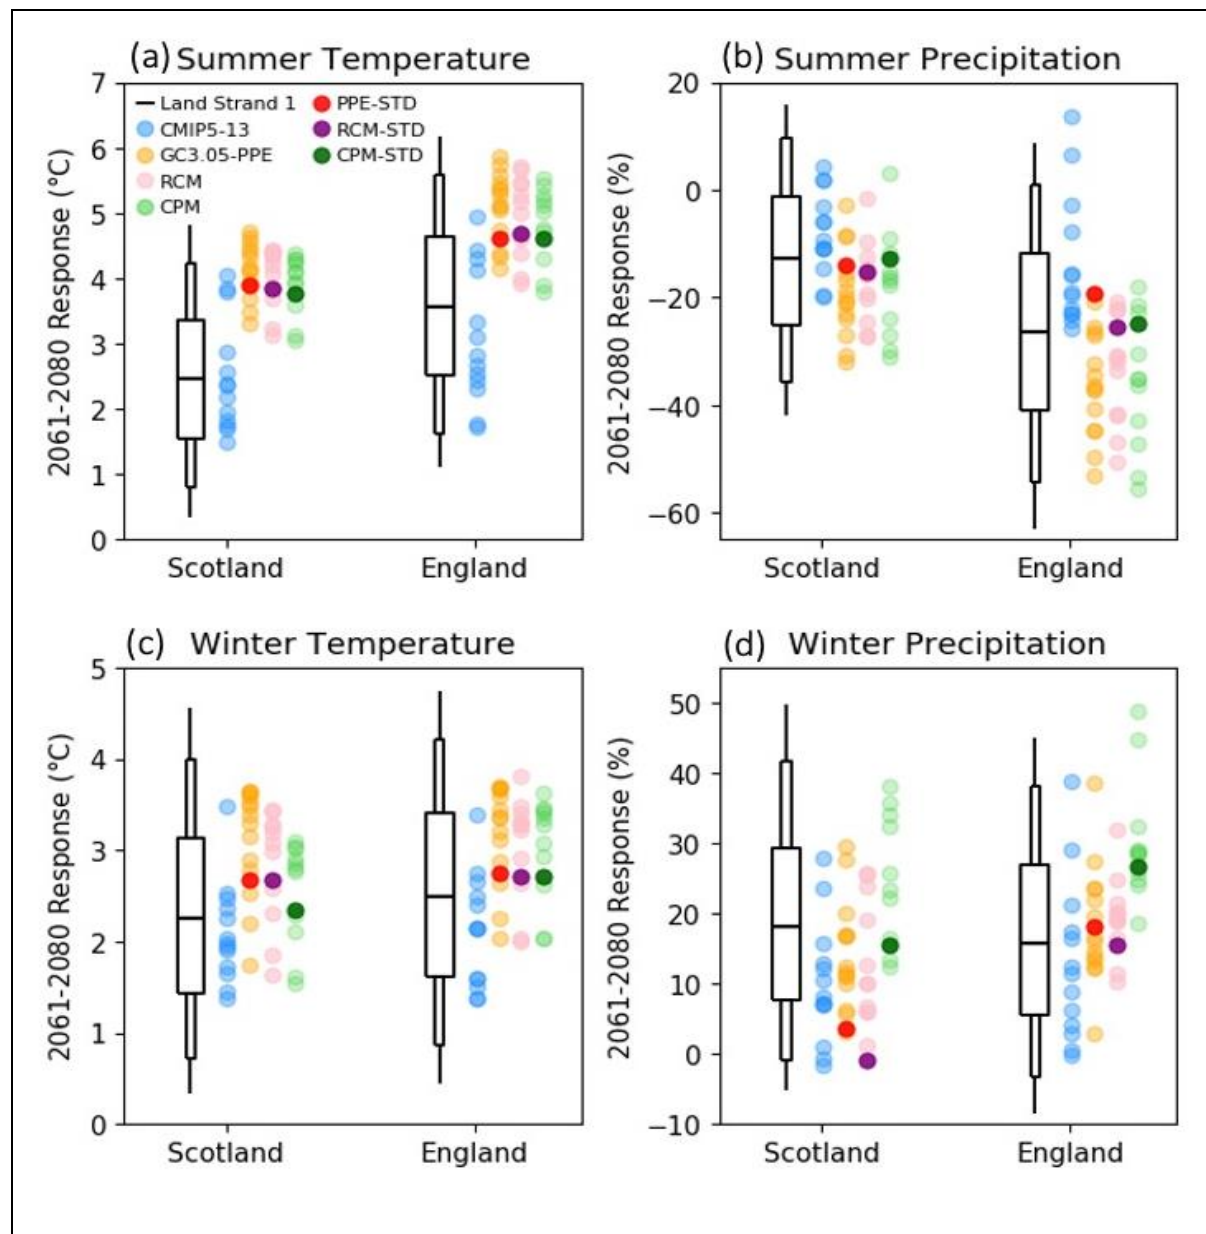

A key point is that while drier summers are generally more likely across the UK, wetter summers are also possible – for most of the country there is a 10% probability of 20-year average summer precipitation increasing by at least 10%. Drier summers are therefore far from certain in the near term. For winter, however, the lower part of the likelihood range remains constant; at any time in the projections, it is about 10% likely that the 20-year mean precipitation would be more than 20%

below that for 1981-2000. So, there is no projected change in the likelihood of dry winter conditions when considering the 20-year mean.

A key question is how the HadGEM3-based projections compare with the UKCP18 probabilistic projections for temperature and precipitation shown in Figures 1.21 and 1.22. A comparison of the projections for 2061-2080 is shown in Figure 1.23. Here the RCP8.5 scenario is used because the projections with HadGEM3 and its related regional simulations were only performed for this pathway.

The new probabilistic projections are given by the black box and whisker diagrams; these include CMIP5 (blue dots) and the new ensemble of HadGEM3 (orange dots). Both CMIP5 and HadGEM3 were used to construct the CCRA3 probabilistic projections. The new 12km regional climate model (RCM) and 2.2km convective permitting model results are shown in the pink and green dots respectively; they are both driven by boundary conditions from the HadGEM3 ensemble (see Annex 1 for more details).

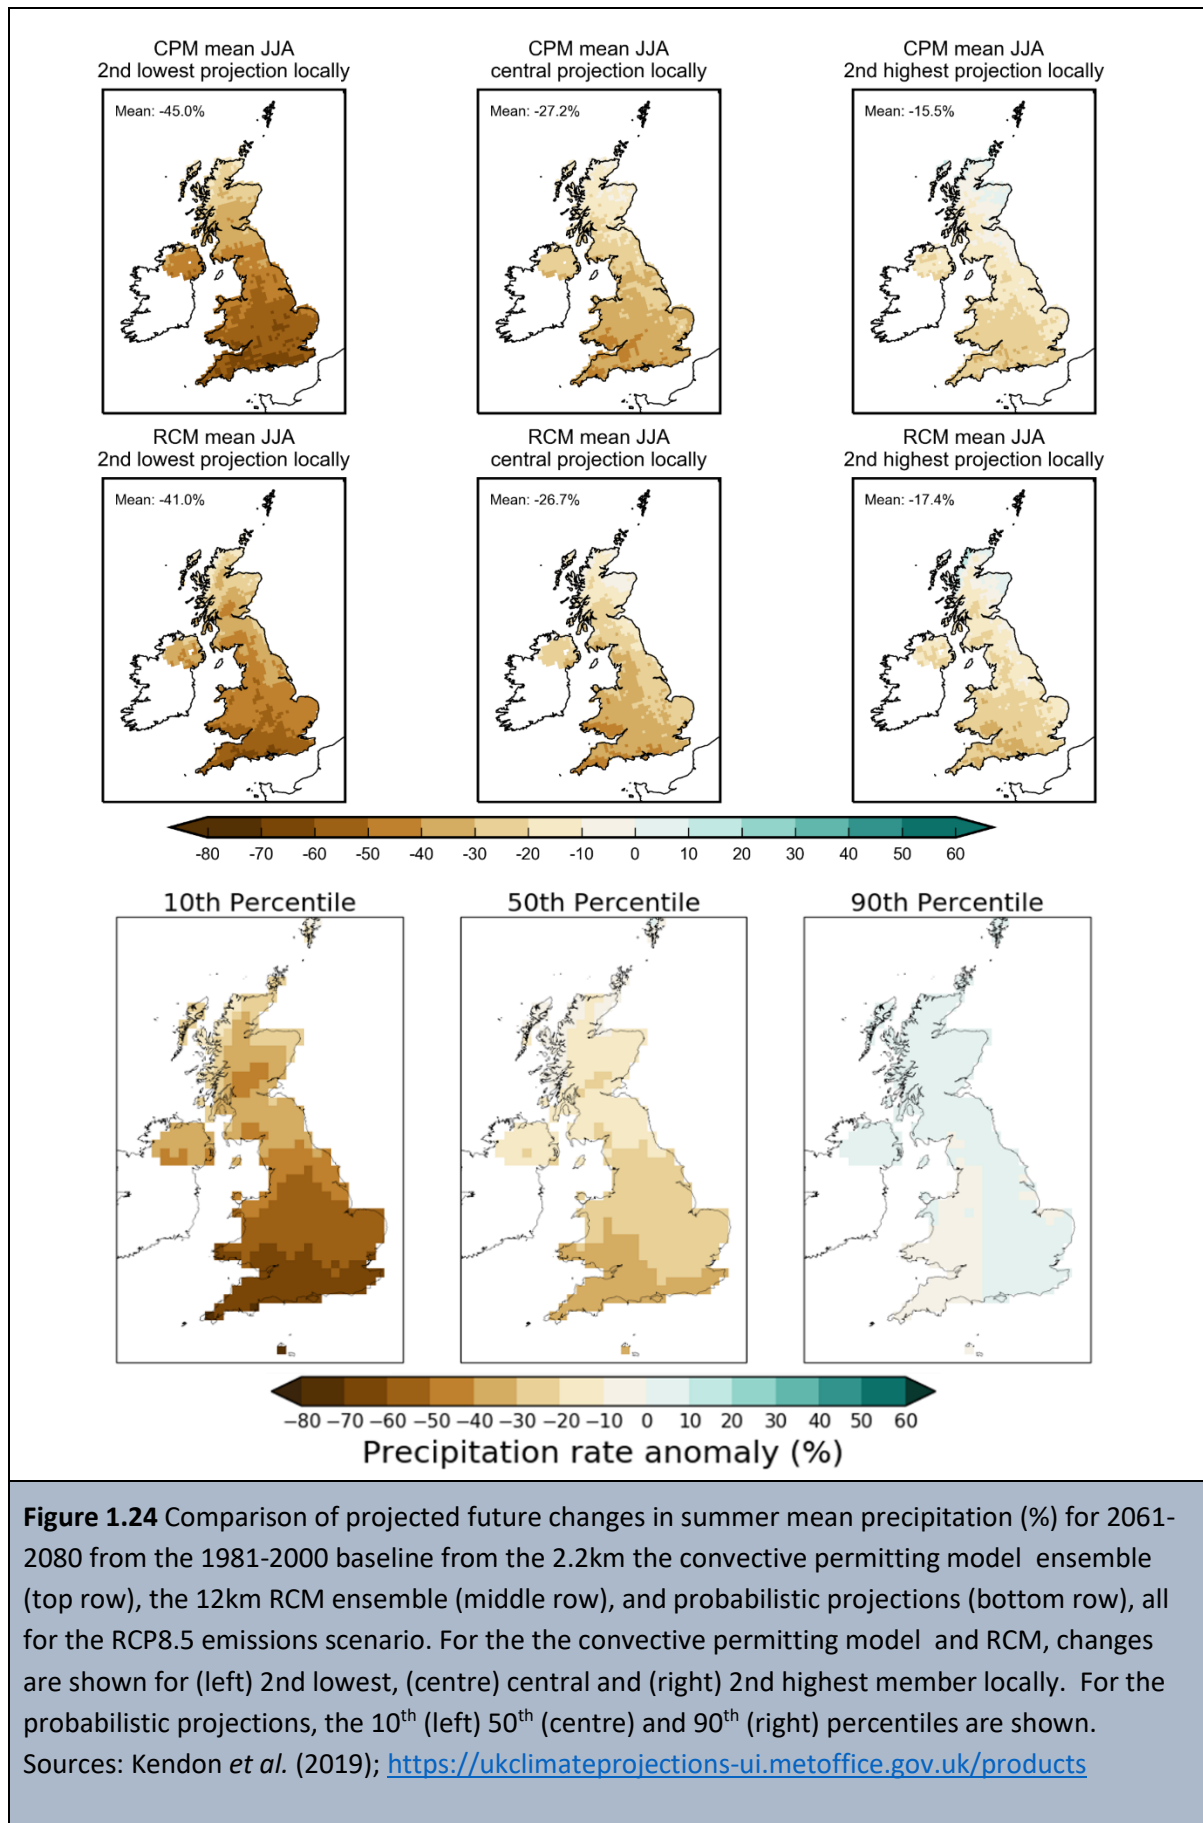

**Figure 1.23** Comparison of seasonal mean changes in surface air temperature (°C) and precipitation (%) across the different UKCP18 products and components, using projected changes with RCP8.5 scenarios, for 2061-2080 relative to 1981-2000, for Scotland and England. (a) and (b) show the changes for summer and (c) and (d) those for winter. Box and whiskers denote the probabilistic projections (Land Strand 1); orange and blue dots denote the HadGEM3 (GC3.05-PPE) and CMIP5 (CMIP5-13) projections respectively. The pink and green dots show the 12km regional model (RCM) and 2.2km convective permitting model projections which use HadGEM3 boundary conditions. The solid dots correspond to the 'standard' HadGEM3 simulation within the full ensemble. The probabilistic projections, GC3.05, RCM and the convective permitting model all use the RCP8.5 emissions scenario and a range of CO<sub>2</sub> concentration pathways accounting for uncertainties in carbon cycle feedbacks. As noted in Section 1.2.3, CMIP5-13 uses a single CO<sub>2</sub> concentration pathway, the standard RCP8.5 concentration pathway, which is at the lower end of the range of the concentration pathways used for the other projections. Reproduced from Kendon, *et al.* (2019)

The introduction of the convective permitting model is particularly important. With kilometre-scale resolution, the convective permitting model not only represents the landscape more accurately, but also captures the fundamental physics of thunderstorms and of embedded convection within weather fronts that is missing in lower resolution models (Kendon *et al.*, 2014). Consequently the representation of extreme sub-daily rainfall and other local extremes, such as wind gusts and high temperatures, has been transformed compared with previous CCRAAs.

In summer, the regional projections are substantially different from the probabilistic projections which incorporate information from CMIP5. HadGEM3 projects hotter and drier summers, a signal that is carried through into the RCM and the convective permitting model results (Figure 1.23(a)). Future increases in temperature over both Scotland and England are projected to be 1-2°C greater than the CMIP5 models. This is associated in part with HadGEM3's higher climate sensitivity and partly with the use of higher CO<sub>2</sub> concentrations in HadGEM3 than CMIP5, because the HadGEM3 projections account for uncertainties in climate-carbon cycle feedbacks (see Annex 1, Figure A1.3 and section A1.4). For England, there is also a very strong signal for much reduced rainfall in summer (Figure 1.23(b)), which itself will also act to elevate summer temperatures. Some of the summer heating may be due to HadGEM3's higher climate sensitivity and higher CO<sub>2</sub> concentrations, but some is clearly associated with changes in the summer atmospheric circulation in HadGEM3 (see Section 1.5.4).

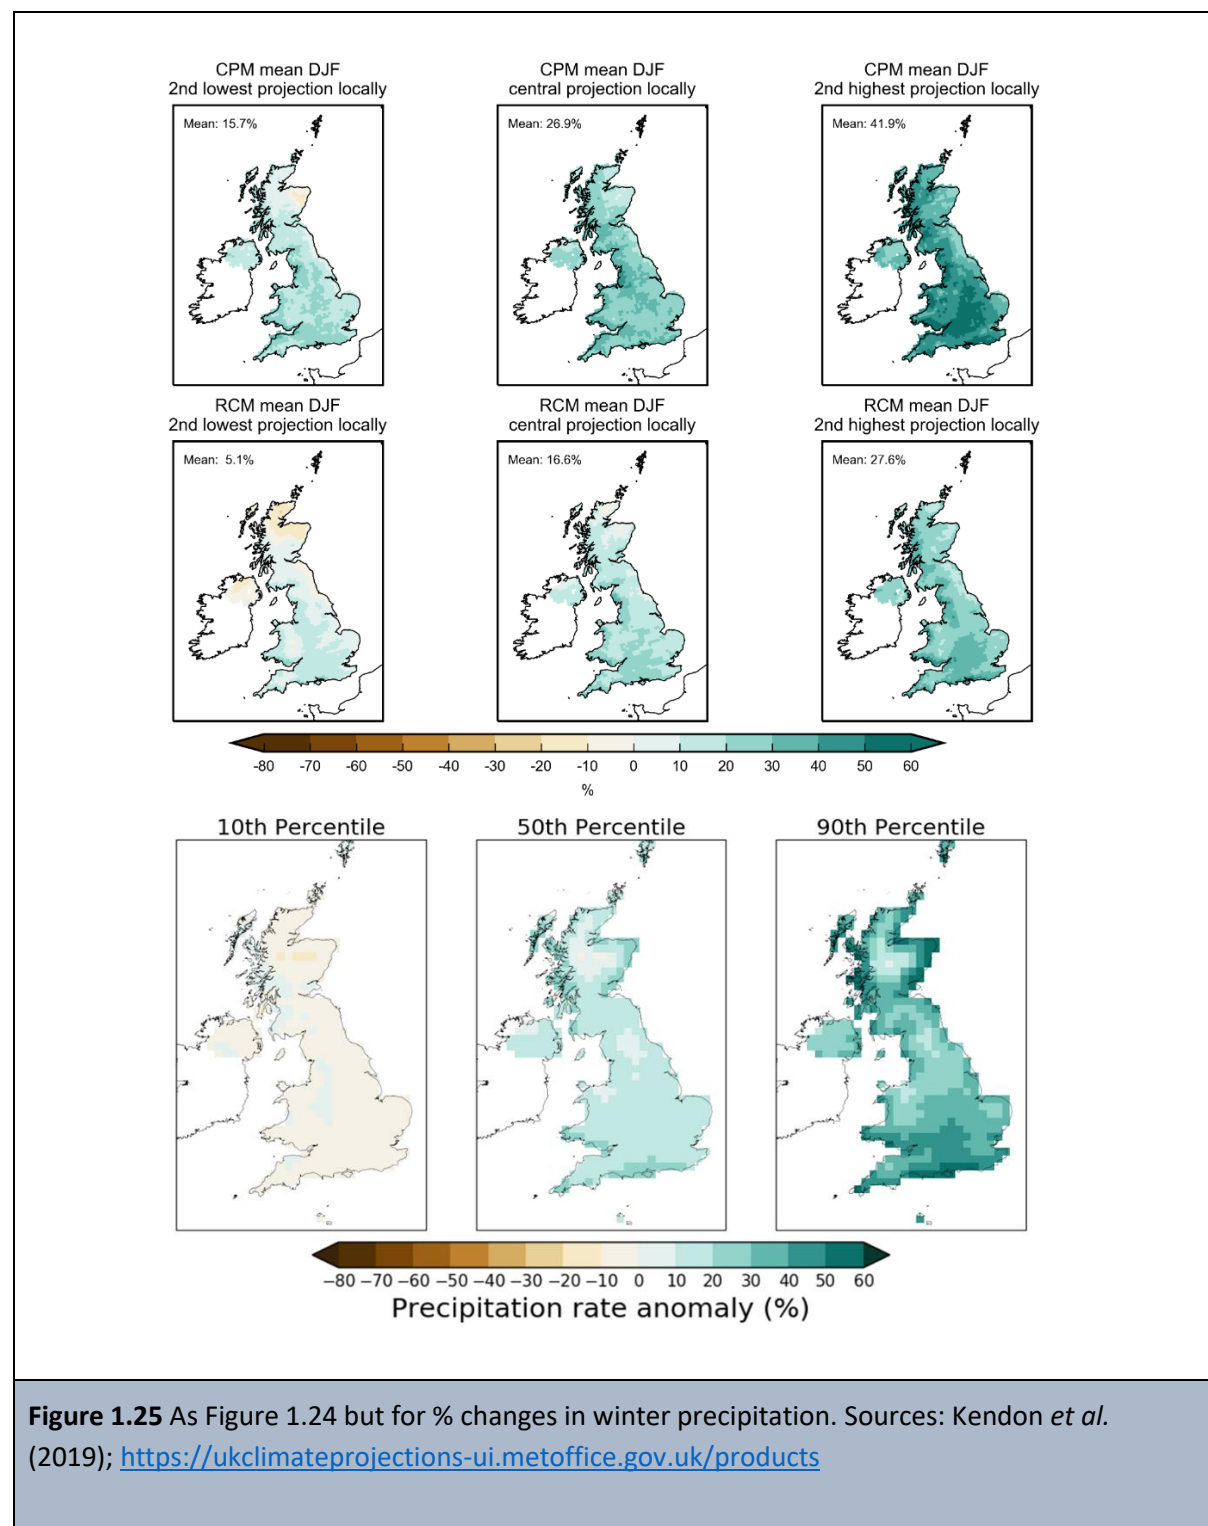

To provide more regional detail, Figure 1.24 compares future changes in the mean summer rainfall from the RCM and the convective permitting model. They are fairly similar which reflects the importance of the driving boundary conditions from HadGEM3. Figure 1.24 also compares these with the 10<sup>th</sup> to 90<sup>th</sup> percentile ranges in the probabilistic projections and shows that this range is larger than those in the RCM and the convective permitting model. While most project decreased precipitation, the probabilistic projections include the possibility of small increases in average summer precipitation over larger areas of the country than in the RCM and the convective permitting model ensembles.

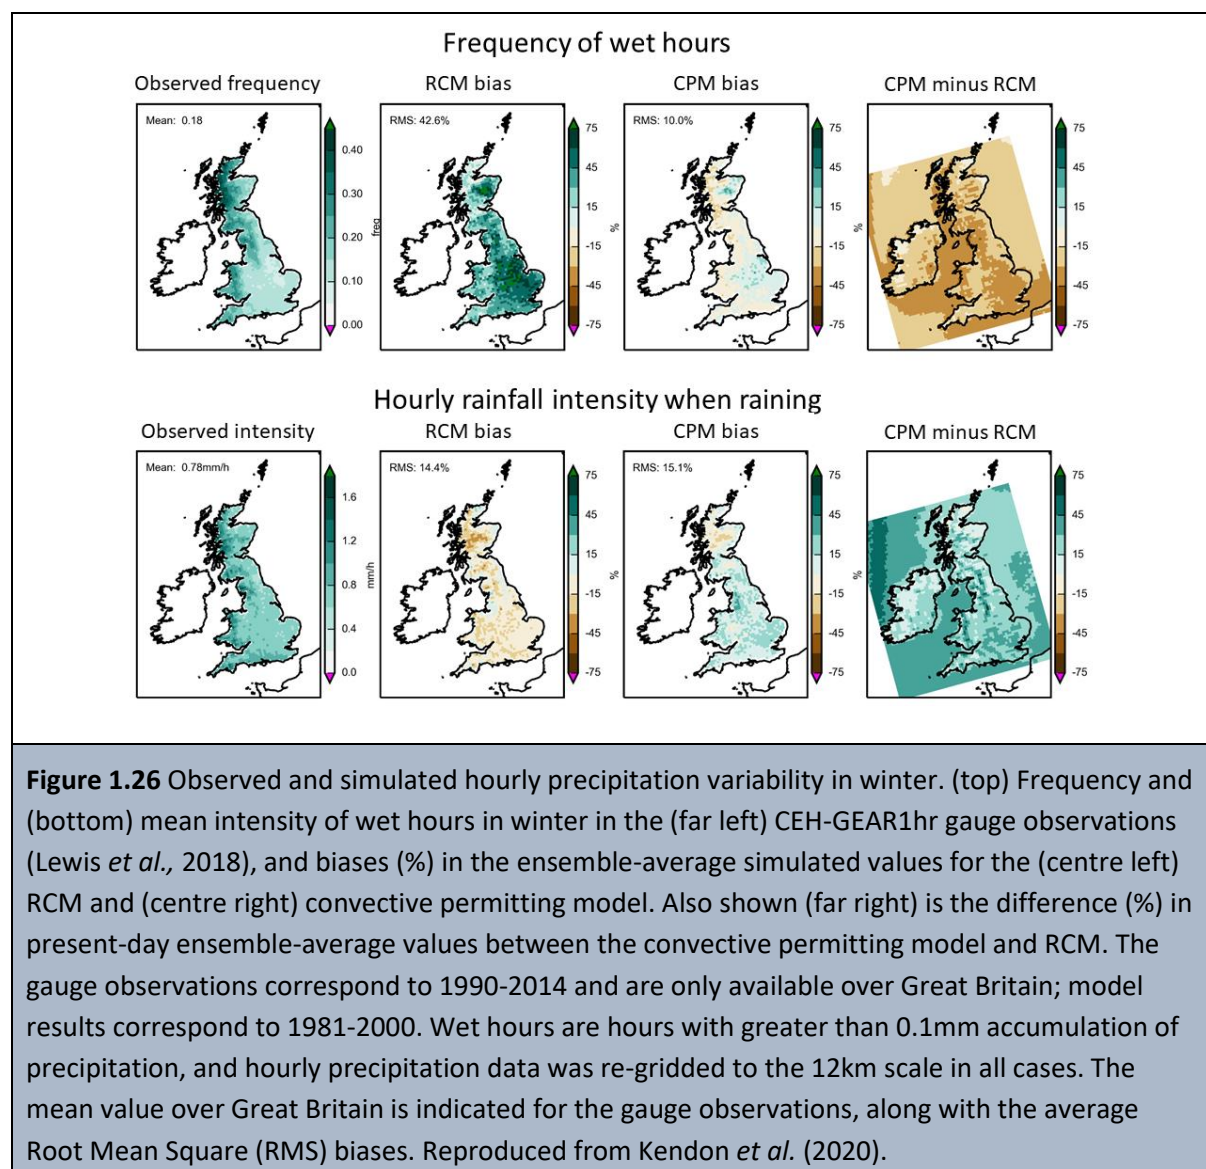

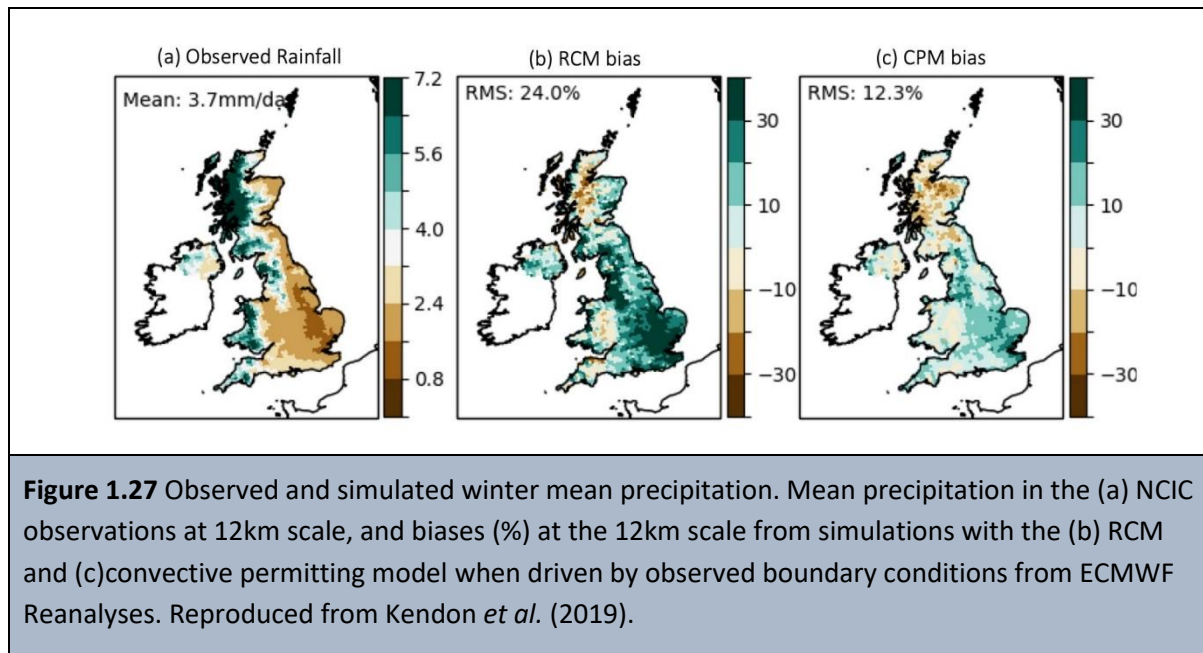

In winter, as shown in Figure 1.23, the results from the various models lie mostly within the range of the probabilistic projections. However, the convective permitting model results show a shift to bigger increases in average precipitation in winter (Figure 1.23) which is countrywide (Figure 1.25).

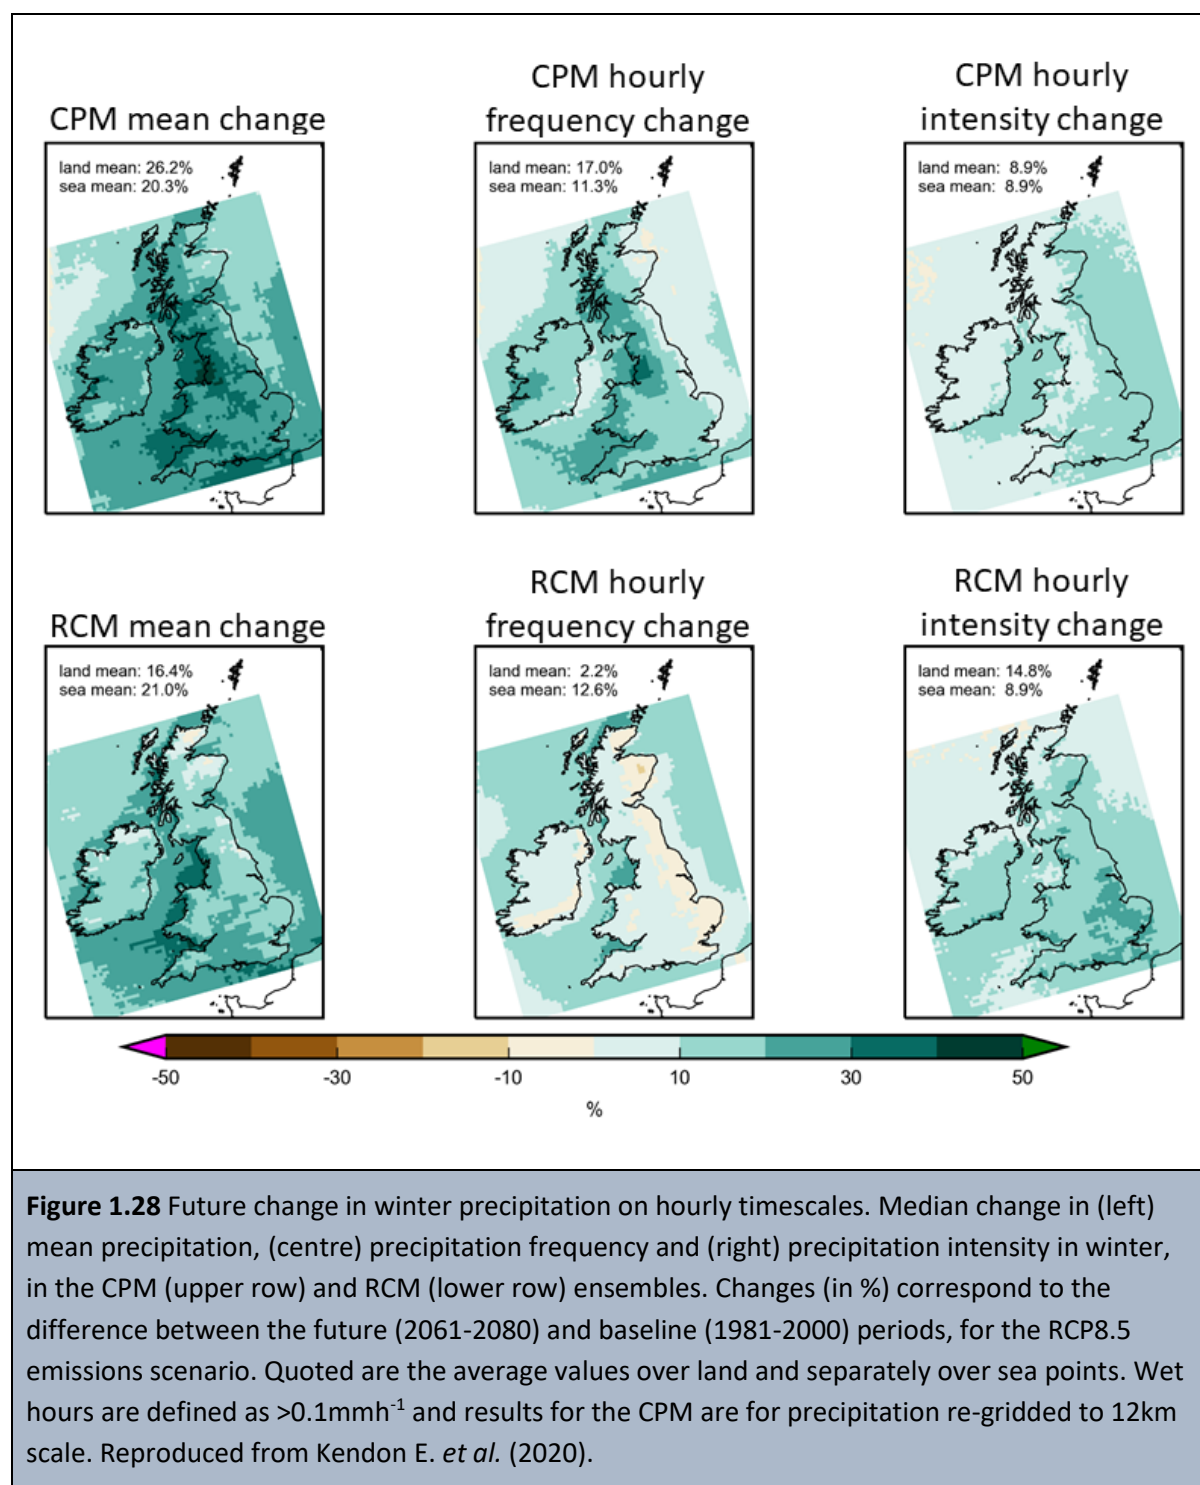

Kendon *et al.* (2020) have linked this increase in winter precipitation in the convective permitting model to the advection over land of convective showers initiated over the sea, a process that lower resolution models do not capture. As in observations, these showers penetrate much further inland in the convective permitting model, bringing more rainfall to the eastern side of the country.

This signal is part of a fundamental difference between the RCM and the the convective permitting model in the nature of winter precipitation. A comparison of hourly precipitation diagnostics with a new observational dataset of hourly precipitation amounts (CEH-GEAR1hr, Lewis *et al.*, 2018) for the current climate (Figure 1.26) shows that the RCM has far too many days when it is raining, and that on those days the rainfall intensity is too low. These biases are largely rectified in the the convective permitting model through *better* representation of the physical processes, as discussed above, giving a simulation that is much closer to observations (Kendon *et al.*, 2020). As a result, the simulation of mean winter precipitation in the the convective permitting model is superior to the RCM for the current climate in a clean test using observed boundary conditions from the ECMWF Reanalyses (Figure 1.27).

Kendon *et al.* (2020) go on to show that, under climate change, the convective permitting model gives both more frequent and more intense rainfall in future over land (Figure 1.28). The frequency increases are considerably larger than in the RCM, with a large part of the convective permitting model's future increases coming from a higher frequency of convective showers. These showers are most likely triggered over the sea (where the warmer ocean and higher levels of atmospheric moisture favour more triggering of convection), and then advected inland, persisting for longer and potentially further development over land. Consequently, as Kendon *et al.* (2020) explain, these showers are an important contributor to the higher winter precipitation response in the convective permitting model; changes in the mean precipitation from convective showers contribute about 40% of the overall change in winter over land in the convective permitting model.

These are important results; they suggest that previous CCRA based on traditional coarser-resolution climate models may underestimate future increases in winter precipitation, especially where wintertime convective showers are a key contributor, since the processes important for the advection and further triggering of showers are only well captured in CPMs. These differences in precipitation frequency and intensity will undoubtedly affect the hydrological response to future rainfall changes, and potentially have implications for river flows, flood risk and water resource management.

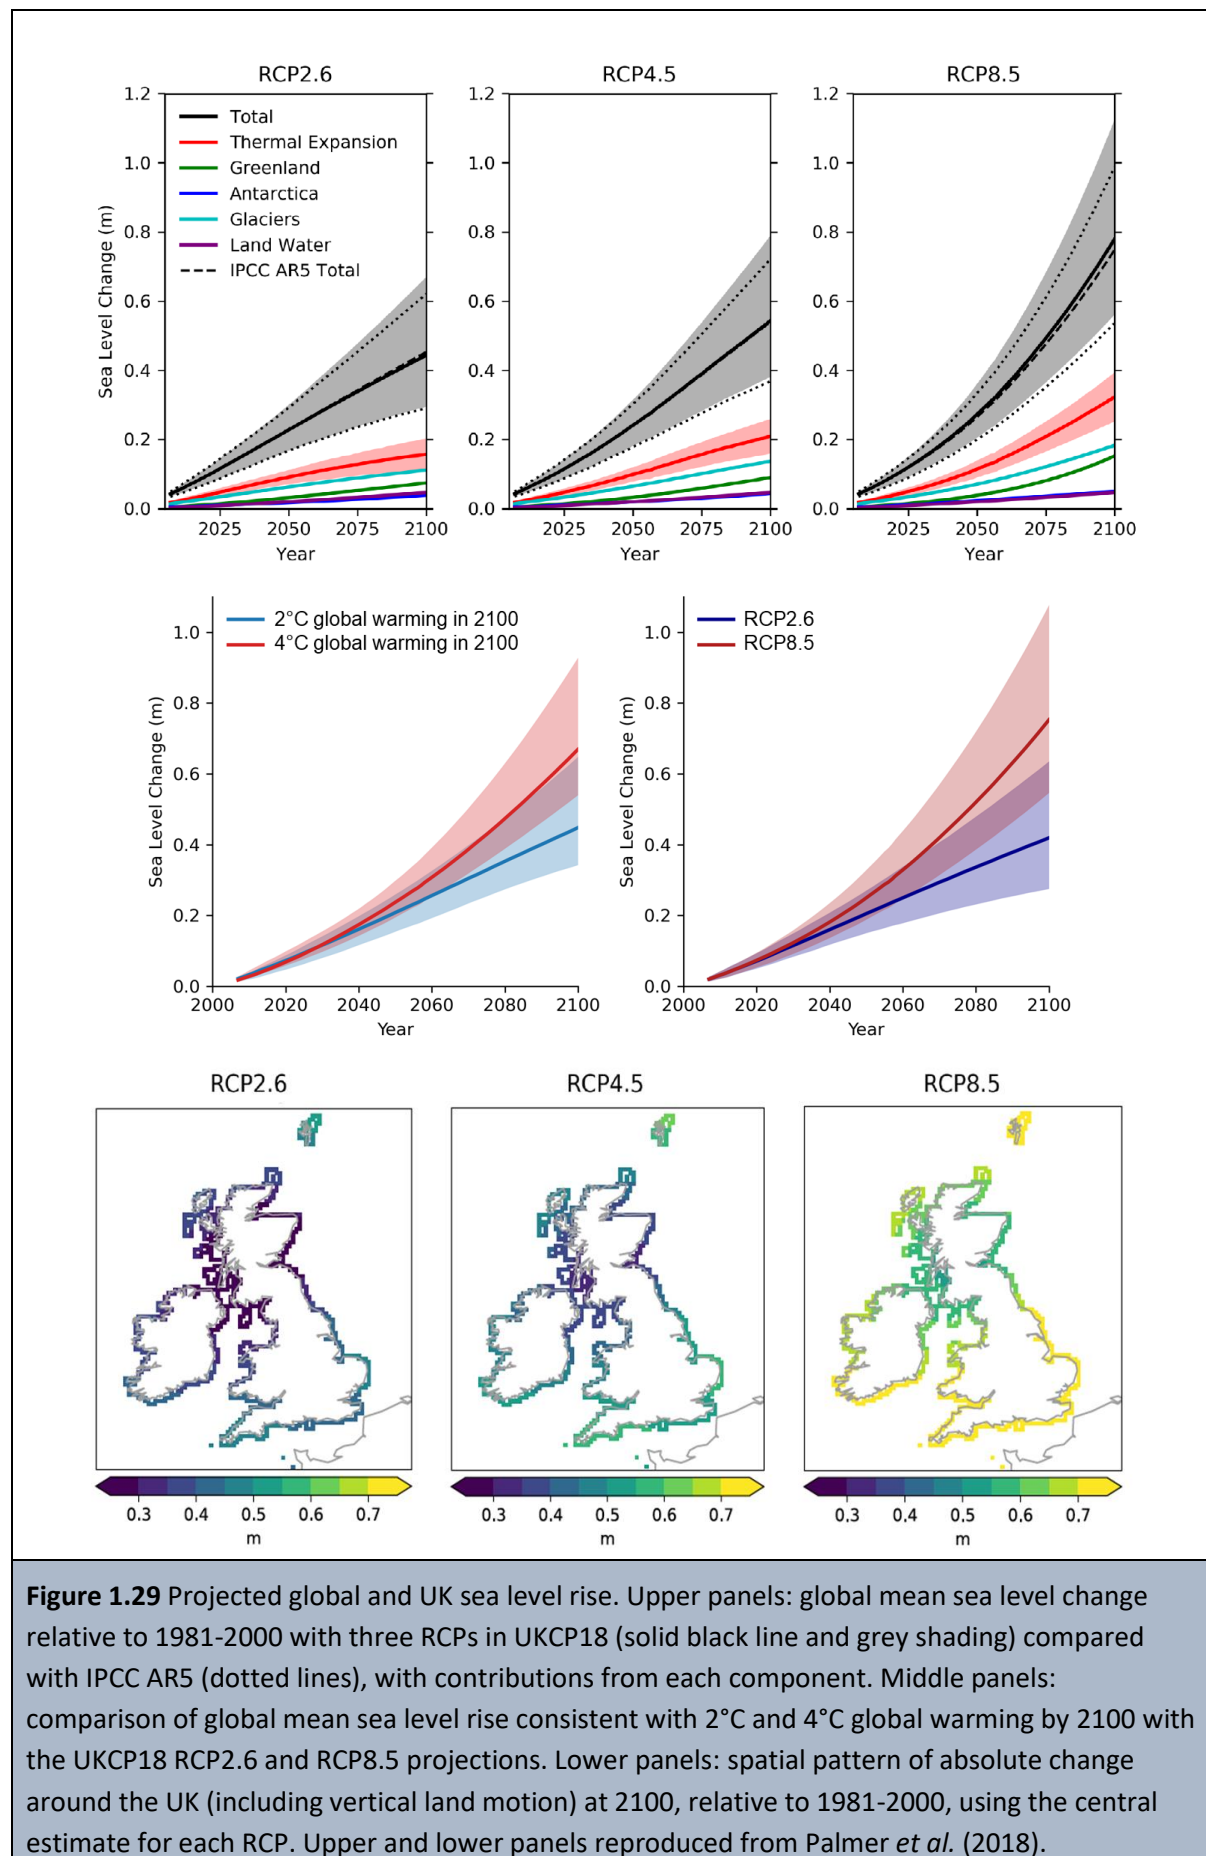

Sea level rise is an important climate impact driver for the UK. Since CCRA2, new assessments of the contributions to current and future sea level rise from the major Greenland and Antarctic Ice Sheets have been derived from observations (suggesting accelerating mass loss) and included in the future projections. Additionally, there have been improvements in the methodology for estimating the range of uncertainties in the UK estimates of local sea rise level (Palmer *et al.*, 2018; Palmer *et al.*, 2020).

Figure 1.29 (upper panels) shows the evolution of global sea level rise through the 21<sup>st</sup> century in the UKCP18 marine projections, using CMIP5 climate scenarios with three concentration pathways. The contributions to sea level rise from the various components are also shown. As in the observations, the thermal expansion of seawater only contributes around one third of the total, emphasising the importance of understanding the vulnerability of the major ice sheets and how mass loss will evolve.

The new estimates in Figure 1.29 include updated estimates of the contribution from Antarctic ice dynamics, which have led to a substantive change in the projections, especially for the 95<sup>th</sup> percentile, indicating an additional 5 - 10cm rise in sea level by 2100 compared with earlier estimates also based on CMIP5 climate projections. However, the processes behind ice sheet collapse particularly for Antarctica remain very uncertain and continued monitoring and process studies are vital. The IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (IPCC, 2019) highlighted that global sea-level rise by 2100 could reach 2m in the most extreme scenarios but viewed this as very unlikely and with low confidence (See Section 1.8 on Earth System Instabilities).

Both the UKCP18 and IPCC AR5 sea-level projections use the CMIP5 climate projections, with UKCP18 using updated methods to project sea level rise resulting from the projected climate changes. It is important to note that the CMIP5 models are driven by the standard RCP projections of concentrations of CO<sub>2</sub> and other greenhouse gases, in contrast with the UKCP18 land projections which are driven by emissions scenarios and account for uncertainties in carbon cycle feedbacks (see Annex 1 A1.4). This means that for any given RCP, the sea level rises in the UKCP18 marine projections are mostly driven by a slower rate of global warming than represented in the UKCP18 land projections (see Figure 1.2).

When subsets of the UKCP18 sea level rise projections consistent with global warming of 2°C and 4°C ( $\pm 0.1$  °C) in 2100 are extracted, these are found to cover much of the likely range of the projections with the RCP2.6 and RCP8.5 concentration pathways (Figure 1.29 middle panels). Therefore the RCP2.6 and RCP8.5 sea level projections can be considered to be reasonably representative of sea level rise consistent with pathways to global warming of 2°C and 4°C ( $\pm 0.1$  °C) in 2100. The RCP8.5 central estimate is about 0.1 m higher than that of the sea level projection consistent with 4°C warming in 2100.

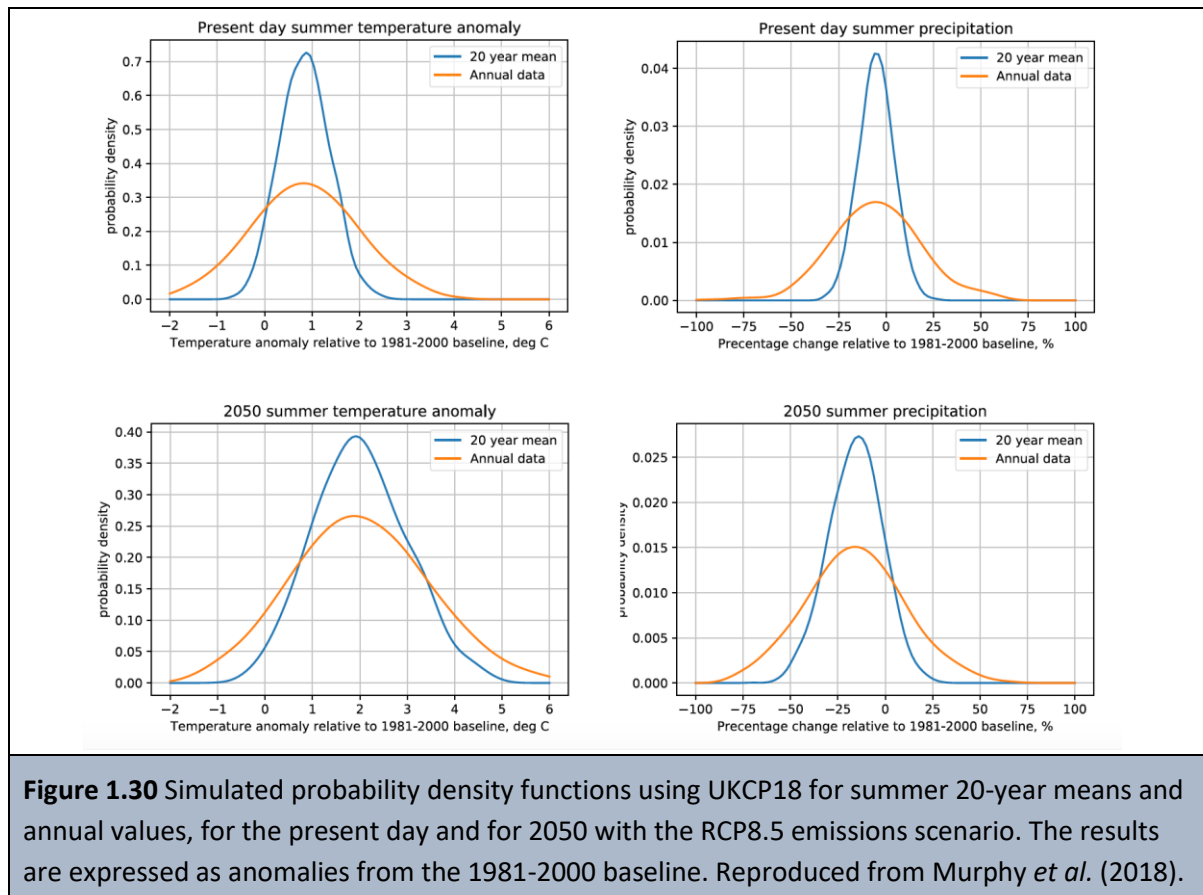

The lower panels of Figure 1.29 show the regional variations in median sea level rise around the UK with the familiar pattern of higher changes in the south. These variations occur due to land-based ice and land water mass loadings, changes in the ocean circulation and the ongoing isostatic adjustment to the last glacial maximum.

Beyond rises in mean sea level many coastal impacts are associated with storm surges. The latest evidence suggests that changes in extreme water levels will likely be more driven by changes in mean sea level than changes in surge, although notable changes in surge (+ or -) cannot be ruled out (Palmer *et al.*, 2018).

### **1.5.3 Moving beyond average climate change: The importance of climate variability on annual timescales**

There is far more evidence in UKCP18 regarding the volatility of the UK's weather and climate going forward, and this provides an improved evidence base for assessing future risks (e.g., Sexton and Harris, 2015). An important new element in UKCP18 is the inclusion of estimates of the envelope of interannual variability; these act to broaden the distribution of probabilities and provide information on changes in the likelihood and intensity of extreme months or seasons going forward.

When interannual variability within any long-term average is included, the spread in the various climatic impact drivers is increased significantly, particularly for variables, such as precipitation, that are highly variable in space and time (Figure 1.30). As Sexton and Harris (2015) note, the spread associated with natural variability is larger for near term climate change, when the forced changes and their inherent uncertainties are smaller. As Figure 1.30 demonstrates, individual summers have high likelihoods of being either wetter or drier than the 20-year average would suggest.

By including the interannual variability in UKCP18 it is possible to look at specific extreme years from the past and to estimate the probability of experiencing such events in the future. Figure 1.31 shows how the probability of experiencing a hot summer like 1976 or 2018 changes with time through the 21<sup>st</sup> century for the RCP8.5 pathway. By the middle of the century the probability of a summer as warm or warmer than 1976/2018 has a projected probability of around 50%, while by the end of the century the probability is greater than 90%; in other words, summers like 1976 and 2018 could become commonplace.

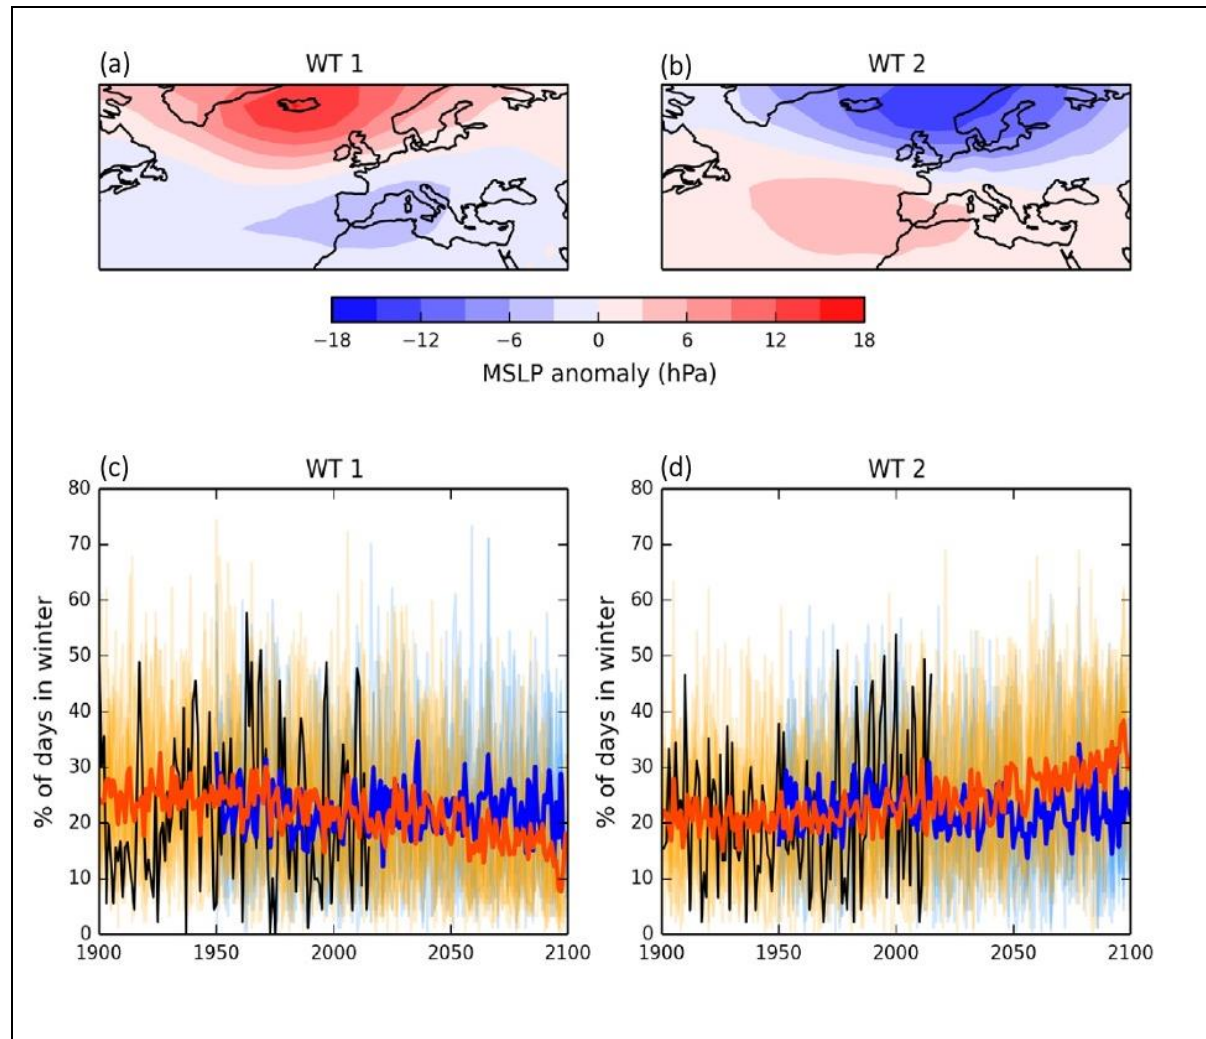

In summary, UKCP18 has delivered a new capability to look beyond changes in the mean climate to consider shifts in the envelope of interannual variability. This provides a much richer evidence base for assessing future climatic impact drivers and provides important links between what we experience today and what we will experience in the future.

#### 1.5.4 Moving beyond average climate change: The importance of weather regimes under climate change.

As discussed in Section 1.2, it is important to look beyond simple metrics of average climate change to consider changes in prevailing weather patterns. As outlined in Section 1.2 and documented in Annex 1, HadGEM3 is a more skilful model in representing the North Atlantic Jetstream, its variability and related weather regimes, which may have a strong influence on the UK's future weather and related impacts. For example, Senior *et al.* (2016) investigated the impact of increasing resolution in HadGEM3 on climate change simulations and noted that although long-term averages

at continental and large scales were largely unchanged, there were important regional impacts, including a greater increase in the frequency of the most intense winter storms at the higher resolution used in UKCP18.

In winter, the UK's weather is dominated by the phase of the North Atlantic Oscillation (NAO), which gives rise to two distinct Weather Types (WT), describing either blocked, colder and drier winters (WT 1) or warmer, wetter and windier winters (WT 2; Figures 1.32(a) and (b)). One of the striking results from UKCP18 is the difference between the CMIP5 and HadGEM3 ensembles in the population of these two distinct weather regimes through the 21<sup>st</sup> century (Figures 1.32(c) and (d)).

**Figure 1.32** Past and future behaviour of the two dominant winter daily weather patterns (WT1 and WT2) that affect the UK, based on the phase of the North Atlantic Oscillation (NAO) and as identified by Neal *et al.* (2016). (a) and (b) show the observed anomalies (hPa) in mean sea level pressure (MSLP) relating WT1 and WT2. Together they describe the negative (a) and positive (b) phases of the NAO. (c) and (d) show the percentage of winter days assigned to each pattern for nine members of the CMIP5-13 ensemble with the RCP8.5 concentration pathway (blue) and the HadGEM3 GC3.05 ensemble with RCP8.5 emissions (orange). The thicker lines show the ensemble mean and the black line represents the historical values. Reproduced from Murphy *et al.* (2018).

Both ensembles capture the mean and year-to-year variability of the observations reasonably well, bearing in mind the short observational record and multi-decadal fluctuations in the NAO. However, whereas CMIP5 suggests no change in the population of these weather types, HadGEM3 shows clear trends towards WT 2 and away from WT 1. This implies that future winter weather may be dominated by more mobile, cyclonic weather systems, with fewer blocked winters. This will affect the western parts of the UK, in particular, and may contribute to more substantial increases in daily precipitation with related flooding, as well as a higher incidence of strong winds and waves. As well as the severity of flooding, its special extent is also higher under the types of strong westerly airflow that are expected to become more common (Wilby and Quinn, 2013).

The projected shift to more mobile, cyclonic winters may also increase the risk of atmospheric river events that bring large amounts of precipitation and are major contributors to severe flooding, particularly for the mountainous regions of the UK (e.g., Lavers *et al.*, 2011). Storm Desmond in 2015 was a notable example, with the classic streamer of moist air being drawn from the Caribbean, carried by a strong Jetstream, and impinging on the mountains of Lake District.

Matthews *et al.* (2018) argue that the long-term warming of the North Atlantic may have increased the chance of such an atmospheric river event. Similarly, a recent study by Payne *et al.* (2020), shows that climate change is likely to increase the frequency of atmospheric river events which, when combined with increased atmospheric moisture due to warming, may make them even more severe, increasing the risk of serious flooding and landslides.

This is important new evidence. Even though average annual trends suggest minimal differences in mean winter precipitation between CMIP5 and HadGEM3, changes in the population of these weather regimes may lead to different impacts associated with storms and heavy rainfall, for example.

As in winter, UK summers are also affected by the population of specific weather regimes. Extreme summer heat, as experienced in 2018, was due mainly to a strongly positive summer NAO (SNAO; e.g. Folland *et al.*, 2009), which is characterised by a high-pressure anomaly over and to the north-east of the UK. The positive phase of the SNAO corresponds to anomalous easterly winds, which bring warm air from continental Europe, as well as more local solar radiation and surface sensible heating. These effects reinforce the temperature response over the UK, resulting in the SNAO being a very important control on UK summer heat.

In addition to influencing summer heat, the SNAO is also an important driver of summer rainfall anomalies. Folland *et al.* (2009) showed that there is a strong, negative correlation between the SNAO and England-Wales precipitation, with a positive SNAO favouring low summer rainfall. Studies of the future behavior of the SNAO have shown a tendency for more positive phases under a warming climate, which would indicate an increased prevalence of high temperatures and drought in the future. However, there are large discrepancies between the change in the SNAO and its projection on to UK precipitation, between the CMIP5 models and HadGEM3 (Figure 1.33). Whereas some of the CMIP5 models suggest increased rainfall with a shift to more positive SNAO conditions, HadGEM3 shows a clear signal for reduced rainfall, consistent with the observed relationship between the SNAO and rainfall.

The strong reduction in precipitation in HadGEM3 in response to changes in the circulation, may therefore be a contributing factor in generating more extreme high temperatures in future summers compared with previous projections. Although more research is needed to understand the physical mechanisms behind these changes in the SNAO and its projection on to UK precipitation, it is important that CCRA3 considers the possible impacts of these more extreme scenarios.

Heatwaves and drought are not the only hazards related to the projected change in the summer climate. Wildfires are increasingly likely and potentially more severe (Arnell *et al.* 2021). Poor air quality, linked for example to surface ozone, is exacerbated by high temperatures (Doherty *et al.*, 2013) and by the prevalence of continental air masses which occur during summer blocking episodes (Royal Society, 2008).

The clear message emerging from these studies is that atmospheric circulation patterns (i.e., weather regimes on timescales of days to weeks and modes of climate variability on timescales from months to decades) remain the dominant influence on UK climate impact drivers, now and into the future. Projections of UK climate change therefore need to be underpinned by climate models that have the capability to reproduce these atmospheric patterns, their spatial and temporal characteristics, if they are to tell us how these may change in a warming world.

This is only now beginning to be realised with the latest generation of high-resolution global climate models although many issues still remain. UKCP18 is the first set of UK climate projections to exploit this new generation of high-resolution projections that can begin to answer the question of what the UK's weather will be like in the future and what this means for our future risks and opportunities.

### 1.5.5 Moving beyond average climate change: Daily climatic impact drivers and extreme events

Changes in daily weather and related short-timescale extremes are a key component of many climatic impact drivers. They are typically localized and hence challenging for global and even regional models, with their coarse granularity, to provide reliable estimates. Through the innovative use of the 2.2km convection permitting model UKCP18 has delivered some important new insights on local climatic impact drivers, not just confined to extremes, but including the impacts of representing convection on winter mean precipitation changes (see Section 1.5.2).

So far, the focus of the convection permitting model results has been on high temperatures and extreme rainfall, but other information (for example on wind extremes, hail and lightning) will gradually emerge as the convection permitting model projections are analyzed further.

#### 1.5.5.1 Extreme Temperatures

The UK record temperature of 38.7°C set in Cambridge in July 2019 has raised the question of whether exceeding 40 °C is possible. A frequency analysis of exceedances for specific high temperature thresholds in the RCM and convection permitting model ensembles, versus the NCIC observations, is documented in Table 1.1. The results are expressed as the number of counts of threshold exceedances for all points (based on 12km grid) and for all days in a 20-year period, across the UK (upper table) and just for London (lower table). Table 1.1 shows the median value and also the range across the model ensembles; these indicate quite a broad spread in the models which, for the current climate (1981-2000), generally encompasses the observations. It is worth noting that counts of 4871 and 184 for the 32°C threshold in the present-day simulation of the convection permitting model, for all-UK and London respectively, correspond to only 0.04% and 0.21% of values. Therefore exceedances of these thresholds are very much in the tail of the temperature distribution and hence subject to quite a bit of noise, especially with only a small model ensemble.

**Table 1.1** Counts of exceeding certain daytime temperatures for 20-year periods from NCIC observations, the RCM and convection permitting model, for all gridpoints over the UK (1614 points; upper table) and London (12 points; lower table) over all days for the current climate (1981-2000) and for future projections (2021-2040; 2061-2080) using the RCP8.5 scenario. All data have been regridded to 12km RCM grid. Thus, the total number of days is 7200 days for the models (360-day calendar) and 7305 days for the observations, and the maximum number of counts is therefore 11,620,800 (11,790,270 for the observations) for all UK land points, and 86,400 (87,660) for London. The numbers show the median count (in bold), and the low to high estimate (in brackets, corresponding to

2<sup>nd</sup> lowest to 2<sup>nd</sup> highest member) counts across the ensemble for the convection permitting model and RCM, compared to NCIC observations, for the 20 years of each timeslice. Source: Met Office.

The results in Table 1.1 show a clear signal of increasing frequencies of high temperature exceedances through the 21<sup>st</sup> century, in accordance with the overall warming. The CPM systematically records higher frequencies than the RCM, even though the mean warming is almost identical (see Figure 1.22). However, the convection permitting model provides a better representation of urban processes and heat-island effects, due to both the high spatial resolution and also the use of the 2-tile MORUSES urban scheme. Importantly, both models show that there is a very small chance of exceeding 40°C by 2040, but that by 2080 the frequency of exceeding 40°C is similar to the frequency of exceeding 32°C today with the RCP8.5 concentration pathway<sup>6</sup>.

<sup>6</sup> The median of the RCP8.5 projections with the CMIP5 multi-model ensemble is consistent with a scenario of 4°C global warming at the end of the century: see Chapter 2: Watkiss and Betts (2021).

Furthermore, the median likelihood of exceeding 40°C by 2080 is three times higher in London than across the whole of the UK (0.16% versus 0.05%).

The potential for the UK to experience daytime temperatures above 40°C has also been demonstrated in an independent study by Christidis *et al.* (2020) using a different methodology. They addressed the question of high temperature exceedances by using observations to relate local extremes to UK-wide mean extremes, and then applying the resulting relationships to 16 CMIP5 global model projections in a risk-based attribution methodology. This enables them to distinguish between high temperatures due solely to natural variability and those that have a contribution from anthropogenic warming, both for the present day and for the late 21<sup>st</sup> century (Figure 1.34).

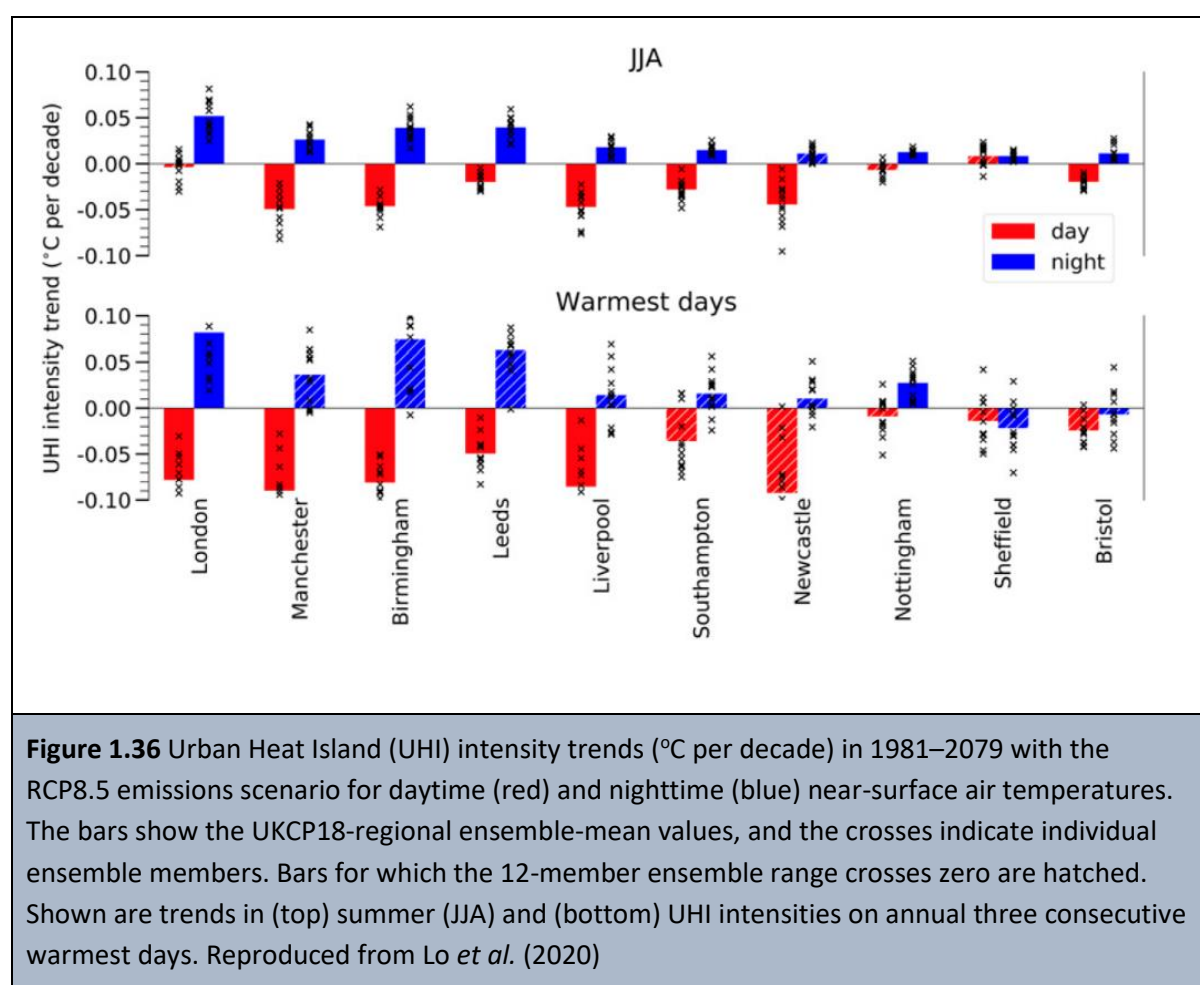

For the present day, the incidence of high temperatures is dominated by natural variability but later in the century human influence dominates. Across the whole of the UK the likelihood, locally, of exceeding 30°C, and even 35°C, increases with time. By 2100 many areas in the north are likely to exceed 30 °C at least once per decade. In the south-east temperatures above 35°C become increasingly common, and temperatures exceeding 40°C also become possible. Summers that experience days above 40°C somewhere in the UK have a return time of 100-300 years at present. This is projected to decrease to 3.5 years by 2100 with the RCP8.5 concentration pathway, which is consistent with a scenario of 4°C global warming at the end of the century (see Chapter 2: Watkiss and Betts, 2021).

Using the UKCP18 RCM projections, Lo *et al.* (2020) have estimated the 1981–2079 trends in summer urban and rural near-surface air temperatures and in urban heat island (UHI) intensities during day and at night in the 10 most populous built-up areas in England. There are larger upward trends in daytime than nighttime temperature for both urban and rural areas (Figure 1.35), where rural areas are defined as those contiguous to the city.

Their results also show a signal of an urban cool island effect during the day but an urban heat island effect during the night (Figure 1.36). For example, by 2080, London's ensemble-mean summer nighttime UHI intensity is projected to increase to 2.1°C, whereas its daytime UHI intensity is projected to decrease slightly to 0.8°C. These summer daytime urban cool islands are likely to be the result of a phase delay in the increase in upward sensible heat flux in the urban areas during the day because of their large thermal inertia (e.g., Bohnenstengel *et al.*, 2014). This means that cities absorb heat during the day and release it at night. The increased intensity of the UHI at night has implications for the frequency of tropical nights in cities with associated heat stress and health implications.

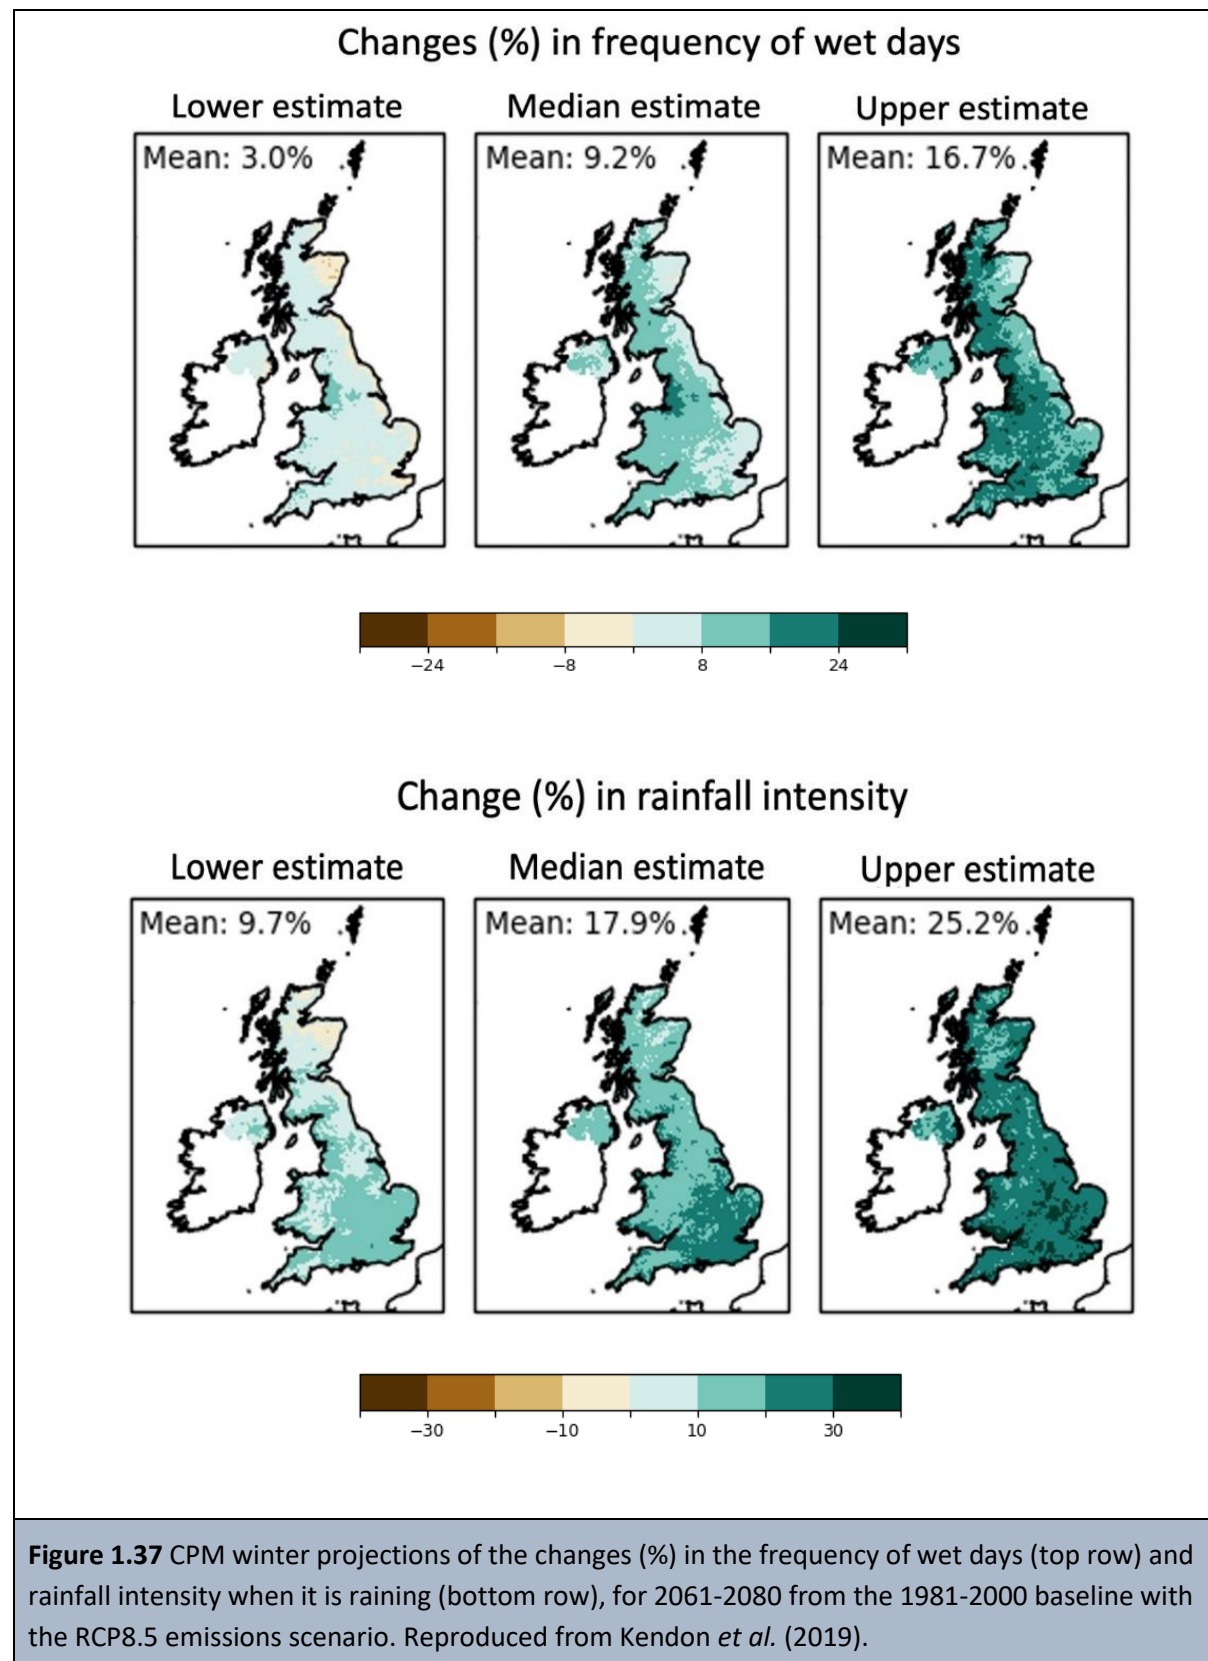

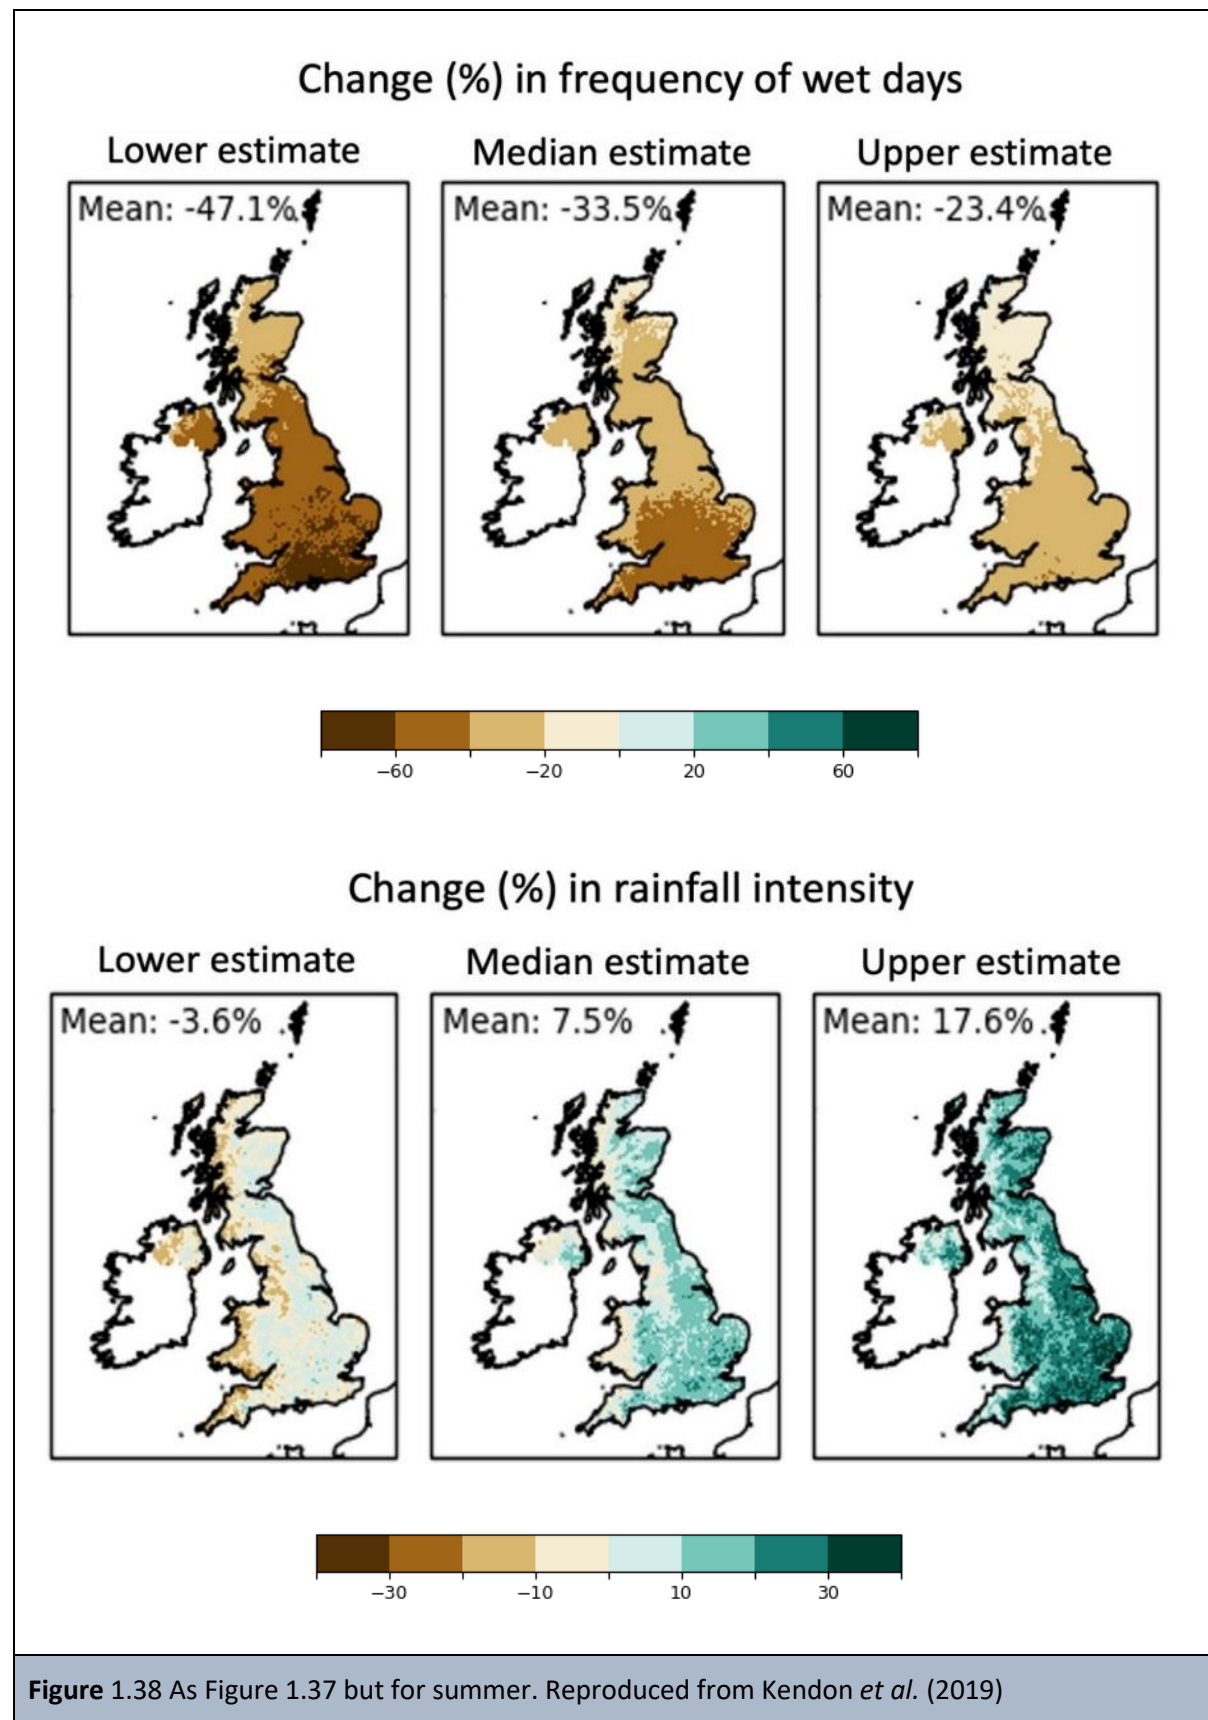

### 1.5.5.2 Extreme Precipitation

The average precipitation is a combination of the frequency of rainfall (often termed wet days) and the intensity of the rainfall when it is raining. Even when the average precipitation is unchanged, there can be shifts between frequency and intensity that have important hydrological consequences. Flooding, water resource management and agriculture are all sensitive to the frequency of rain days and how intense the rain is when it falls.

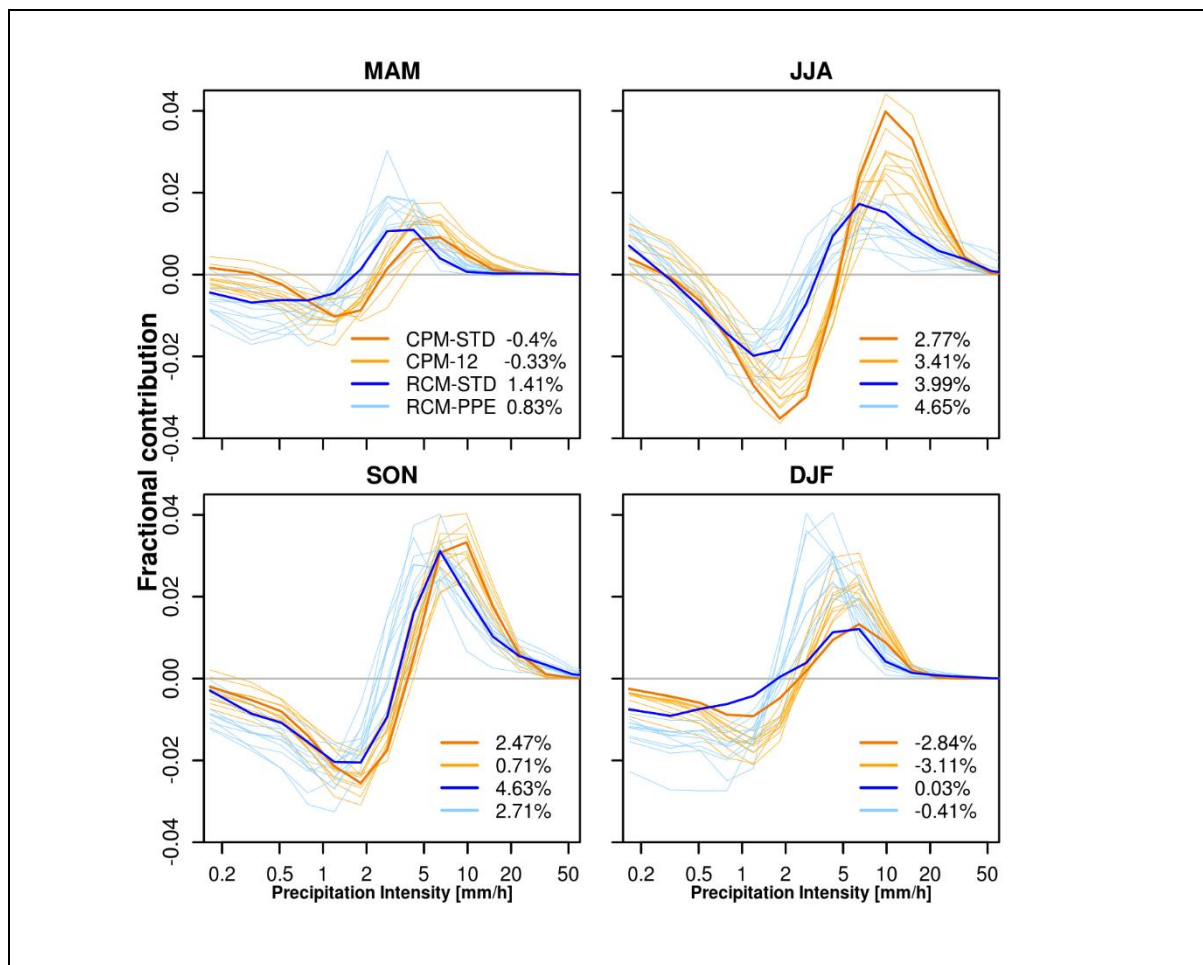

The convection permitting model has proved to be particularly effective in capturing the frequency versus intensity of precipitation (e.g., Kendon *et al.*, 2019) and for simulating extreme daily and sub-daily precipitation (e.g., Kendon *et al.*, 2014). This is because the convection permitting model is able to resolve much more of the physics of rain-bearing systems, as well as resolving the local landscape, especially mountainous terrain, with much greater fidelity than the RCM and global models.

The mean signal of wetter winters is a combination of more wet days (Figure 1.37 top row), as well as an increase in the intensity of rainfall (Figure 1.37 bottom row), which is projected to increase by as much as 25%, particularly in the south-east. The same analysis for summer (Figure 1.38 shows that despite overall summer drying, with wet days projected to become less frequent, the convection permitting model projections nevertheless suggest that when it does rain, the rainfall will be more intense.

Sub-daily and hourly precipitation rates are important drivers of flash flooding events. Figure 1.39 shows future changes in the shape of the hourly precipitation distributions from the RCM and convection permitting model. There is clear evidence of a shift to more intense hourly rainfall at the expense of lighter rainfall in all seasons, in both models, and for all ensemble members. In autumn and winter, changes in the shape of the wet value distribution are very similar between the convection permitting model and RCM. The greatest difference in changes between the models is seen in summer, where there is a much greater increase in the fractional contribution from high intensities in the convection permitting model. This is consistent with Kendon *et al.* (2014) who showed that in the convection permitting model summer convective storms are strengthened by local dynamical feedbacks.

**Figure 1.39** Future change in fractional contribution of hourly precipitation intensities to total precipitation for all seasons. Plotted is the future change in the fractional contribution of hourly precipitation events within 17 different intensity bins to total UK rainfall, for wet events only ( $>0.1\text{mm/h}$ ), in different seasons. The contributions were calculated by assigning each wet hour from every 12km UK grid box to the relevant intensity bin and multiplying the number of counts in each bin by the average intensity; these contributions are then divided by the total precipitation across all bins to give the fractional contribution. Future changes are differences between 2061-80 and 1981-2000 periods, for convection permitting model (CPM-12) (orange) and RCM-PPE (blue) members, using the RCP8.5 emissions scenario, with dark lines for the standard member.

Future changes in the percentage of dry hours (in %) are indicated in the figure legends (corresponding to standard members and ensemble-average value for CPM-12 and RCM-PPE). Intensity bin boundaries are: 0.1, 0.23, 0.41, 0.62, 0.95, 1.4, 2.2, 3.4, 5.1, 7.8, 11.9, 18.1, 27.5, 42.0, 63.9, 97.4, 148 and 500 mm/h. Reproduced from Kendon *et al.* (2019).

Overall, as Figures 1.37 to 1.39 show, there are large changes in the frequency and intensity of daily and hourly precipitation. The hydrological implications of these major shifts in precipitation characteristics for both winter and summer could be profound.

Urban flash flooding is an increasing problem as heavy, sub-daily rainfall events become more frequent. Using the convection permitting model ensemble as an event set, the frequency of precipitation exceeding 30mm/hour has been analysed for some UK cities for present-day (1981-2000) and future (2061-2080) periods with the RCP8.5 emissions scenario (Table 1.2). This methodology, which follows UNSEEN described in Section 1.4, enables more robust estimates of return times for rare events. The results show that currently the return period for such events is typically around 10 years, but the return period decreases to around 5 years by 2080.

**Table 1.2** The changing frequency of precipitation exceeding 30mm/hour for 4 cities around the UK expressed as the number of instances per year based on the 12-member ensemble with the convection permitting model. Source: Met Office

Location	Present Day (1/year)	Future (1/year)	Frequency Change
Greater London	0.095	0.139	x 1.5
Edinburgh	0.054	0.099	x 1.8
Belfast	0.136	0.233	x 1.7
Cardiff	0.092	0.191	x 2.1

### 1.5.6 Summary of Evidence of Future Changes

The new generation of Met Office models that underpin UKCP18 has generated some significant changes to the previous evidence used in CCRA2, such as increased winter rainfall and summer drying, as well as new evidence of physically plausible changes in local extremes on daily and sub-daily timescales. The framing of future climatic impact drivers in terms of changes in weather and climate regimes has been a new feature of the analysis and has emphasized the importance of model skill in representing these regimes.

The main results can be summarized as follows:

- The overall message of future winters becoming warmer and wetter still prevails. However, the changes in rainfall are likely to be more extreme than was anticipated in previous CCRA2s. The mean signal of wetter winters is a combination of more wet days, as well as an increase in the intensity of daily rainfall, which is projected to increase by as much as 25%, particularly in the

south-east. This increase in rainfall intensity potentially implies an enhanced risk of surface water flooding.

- Future winter weather may be dominated by more mobile, cyclonic weather systems, with fewer blocked winters than was the case in previous assessments. This will affect the western parts of the UK, in particular, and may contribute to more substantial increases in daily precipitation with related flooding, as well as a higher incidence of strong winds and waves. The projected shift to more mobile, cyclonic winters may also increase the risk of atmospheric river events that bring large amounts of precipitation and are major contributors to severe flooding, particularly for the mountainous regions of the UK.
- Future summers are projected to be even hotter and drier than earlier estimates. Reductions in rainfall are substantially larger over England, typically double those used in CCRA2. This can be attributed to improved simulations of summer circulation anomalies as well as higher temperatures. Despite overall summer drying, with wet days projected to become less frequent, the new kilometer-scale projections suggest that when it does rain, the rainfall will be more intense by as much as 20%.
- Better representation of the landscape and urban areas have highlighted more frequent and more severe extreme daily high temperatures and urban heat island effects. There is a very small chance of exceeding 40°C by 2040, but by 2080 on a pathway to 4°C global warming at the end of the century, the frequency of exceeding 40°C is similar to the frequency of exceeding 32°C today. Also, night-time urban heat island effects are expected to be more intense, leading to more 'tropical nights' in major cities.
- Sub-daily and hourly precipitation rates show pronounced shifts to more intense hourly rainfall at the expense of lighter rainfall, than in previous assessments. This has serious hydrological consequences including for flash flooding events.

## 1.6 An alternative view: UK climate change for specific levels of global warming

As well as assessing climatic impact drivers for specific time horizons, it can also be helpful to assess them at specific levels of global warming, e.g., 2°C above the pre-industrial state. International climate policy discussions and agreements under the UNFCCC, such as the Paris Agreement, currently frame global goals in terms of levels of global warming to be avoided. Moreover, when comparing multiple climate projections from different models with different emissions scenarios, different climate sensitivities and GHG concentrations, the use of specific time horizons can make it difficult to disentangle new evidence on climatic impact drivers from the diversity of warming rates. The use of global warming levels (GWLs) allows a systematic comparison of different sources of evidence on impacts, if the relevant climate quantities scale linearly with global mean warming, as is generally the case for many climate metrics. RCMs suggest that extreme weather metrics may also scale linearly with global mean warming, but whether this is the case for convection permitting models, and especially extreme precipitation, is still to be explored.

Rather than repeating earlier figures, this section will summarise some additional climatic impact drivers at specific global warming thresholds, based on the study by Hanlon *et al.* (2021a), and the research by Johns (2021), commissioned for CCRA3. These will focus on metrics and threshold exceedances that directly affect the natural environment, agriculture, transport, energy supply,

infrastructure and human health. The metrics and threshold exceedances are those used currently for assessing weather impacts; these have been developed by the Natural Hazard Partnership (NHP)<sup>7</sup> and form part of the National Severe Weather Warning Service (NSWWS)<sup>8</sup>. They are also part of a designated set of climate variables by the WMO Expert Team on Climate Change Detection and Indices (ETCCDI)<sup>9</sup>. The definitions of the variables shown in this section are given in Annex 2. This analysis is similar to that reported by Arnell *et al.* (2020) based on statistical downscaling of the UKCP18 global projections.

Figure 1.40 focuses on cold season impact drivers, specifically frost days, icing days and heating degree days (HDD – see Annex 2 for definition). These are documented for the current climate from the NCIC observations, and from the 21-year averages of regional model climate scenarios centred around specific global warming thresholds - 1.5°C, 2°C, 3°C and 4°C above the average for 1850-1900.

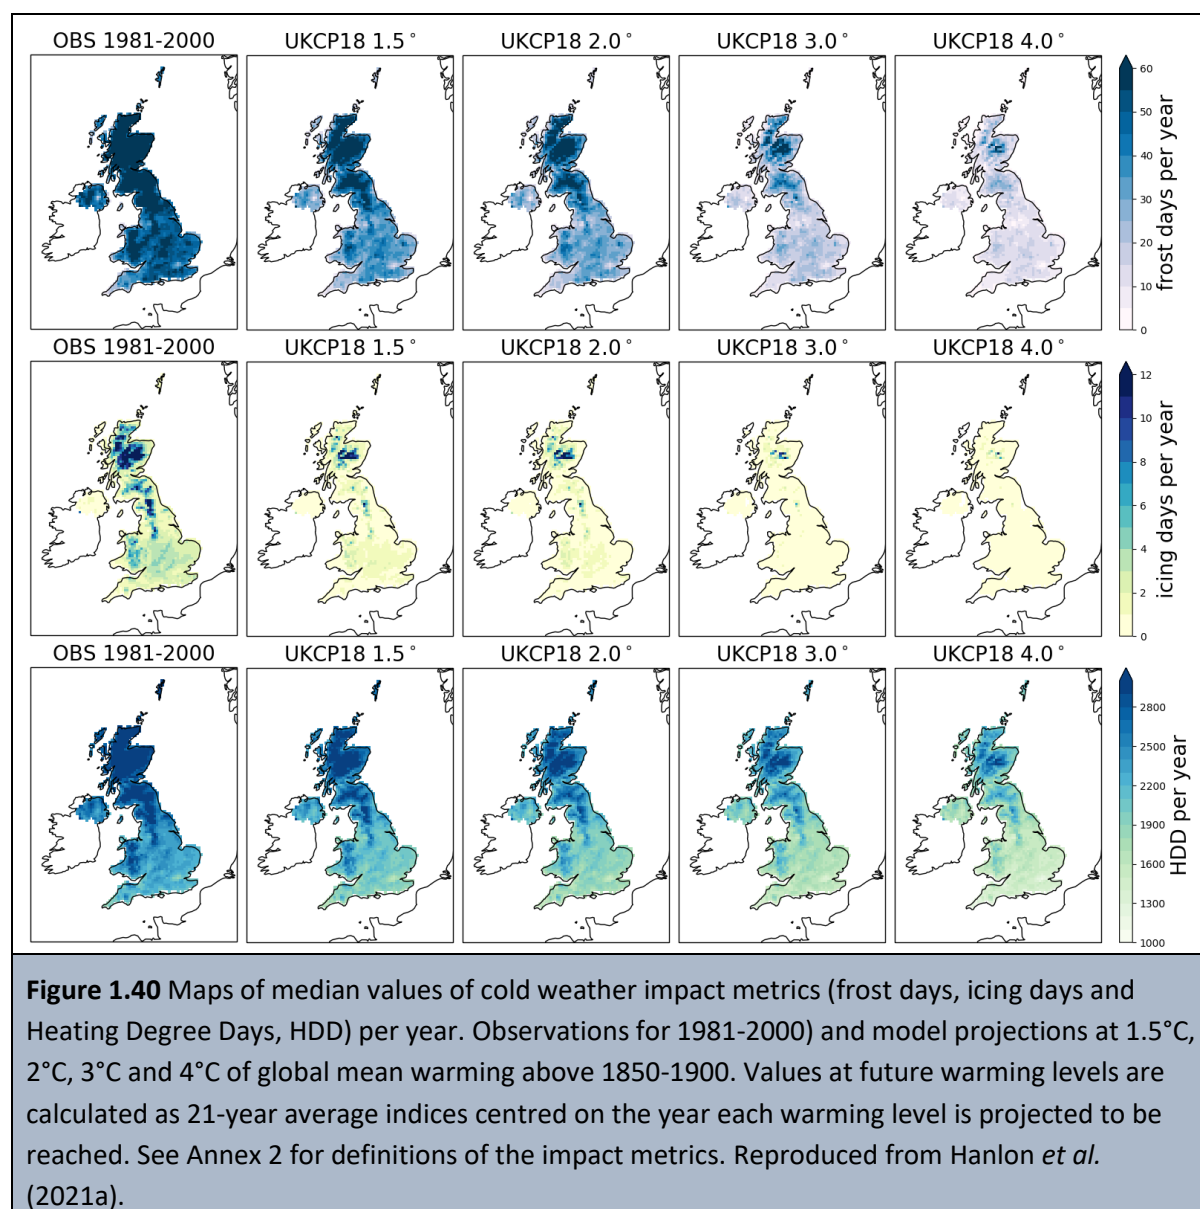

---

<sup>7</sup> Natural Hazard Partnership (NHP): The NHP provides authoritative and consistent information, research and analysis on natural hazards for the development of more effective policies, communications and services for civil contingencies, governments and the responder community across the UK. It is delivered through a partnership between academia, research organisations, public sector bodies and government departments. See <http://naturalhazardspartnership.org.uk/>

<sup>8</sup> National Severe Weather Warning Service (NSWWS): The NSWWS is a service provided by the Met Office to warn the public and emergency responders of severe or hazardous weather which has the potential to cause danger to life or widespread disruption. See <https://www.metoffice.gov.uk/weather/guides/severe-weather-advice>

<sup>9</sup> WMO Expert Team on Climate Change Detection and Indices (ETCCDI): The ETCCDI has the mandate to address the need for the objective measurement and characterization of climate variability and change. The team provides international coordination and collaboration on climate change detection and the indices relevant to climate change detection, and encourages the comparison of modelled data and observations. See: <https://www.wcrp-climate.org/etccdi>

The results show firstly that there is a decline in cold weather metrics even at 1.5°C warming, compared with the observations. Second, there is very little difference in the various metrics between 1.5°C and 2°C, but there are more substantial reductions in cold season impacts at higher warming levels, with icing days almost eliminated for global warming levels of 3°C and above. Heating Degree Days (HDD)<sup>10</sup> are typically 50% lower than today at 4°C global warming.

In summer, the impact metrics revolve around higher temperatures and extended growing seasons. Figure 1.41 shows how the numbers of summer days, tropical nights, Growing Degree Days (GDD)<sup>11</sup>

<sup>10</sup> Heating Degree Days (CDD) are calculated as the product of the number of days below 15.5°C and the number of degrees below 15.5°C on each day where the temperature falls below that threshold.

<sup>11</sup> Growing Degree Days (GDD) are calculated as the product of the number of days above 5.5°C and the number of degrees above 5.5°C on each day where that threshold is exceeded.

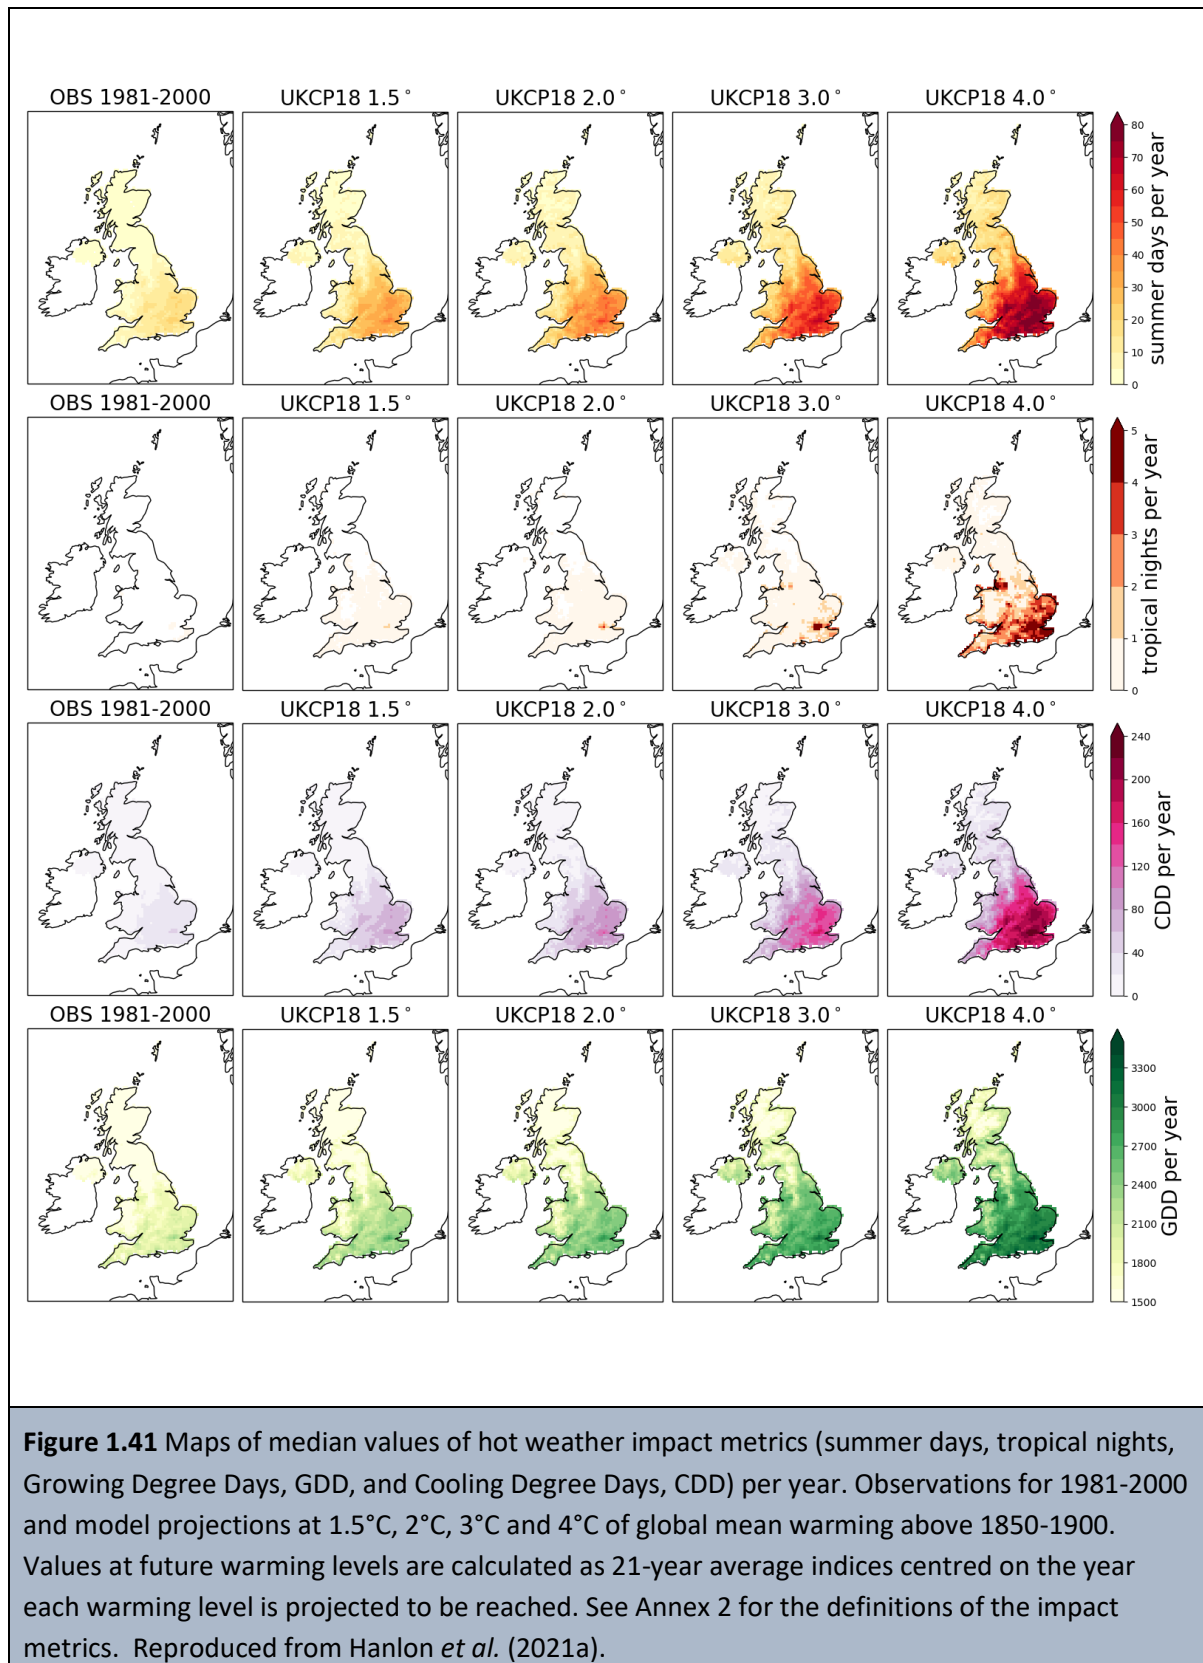

and Cooling Degree Days (CDD)<sup>12</sup> increase with global warming (see Annex 2 for definitions). Compared with cold season impacts, there is a greater difference in summer impacts between 1.5°C and 2°C global warming. There is a substantial increase in summer days as global warming increases, but outside London, tropical nights only become a serious problem at warming levels approaching 4°C and tend to be concentrated in the south-east and in urban regions around Manchester. With warmer days and nights, the number of cooling degree days increases quite rapidly even for 1.5°C and 2°C global warming, indicating the potential for increased energy demand for air conditioning.

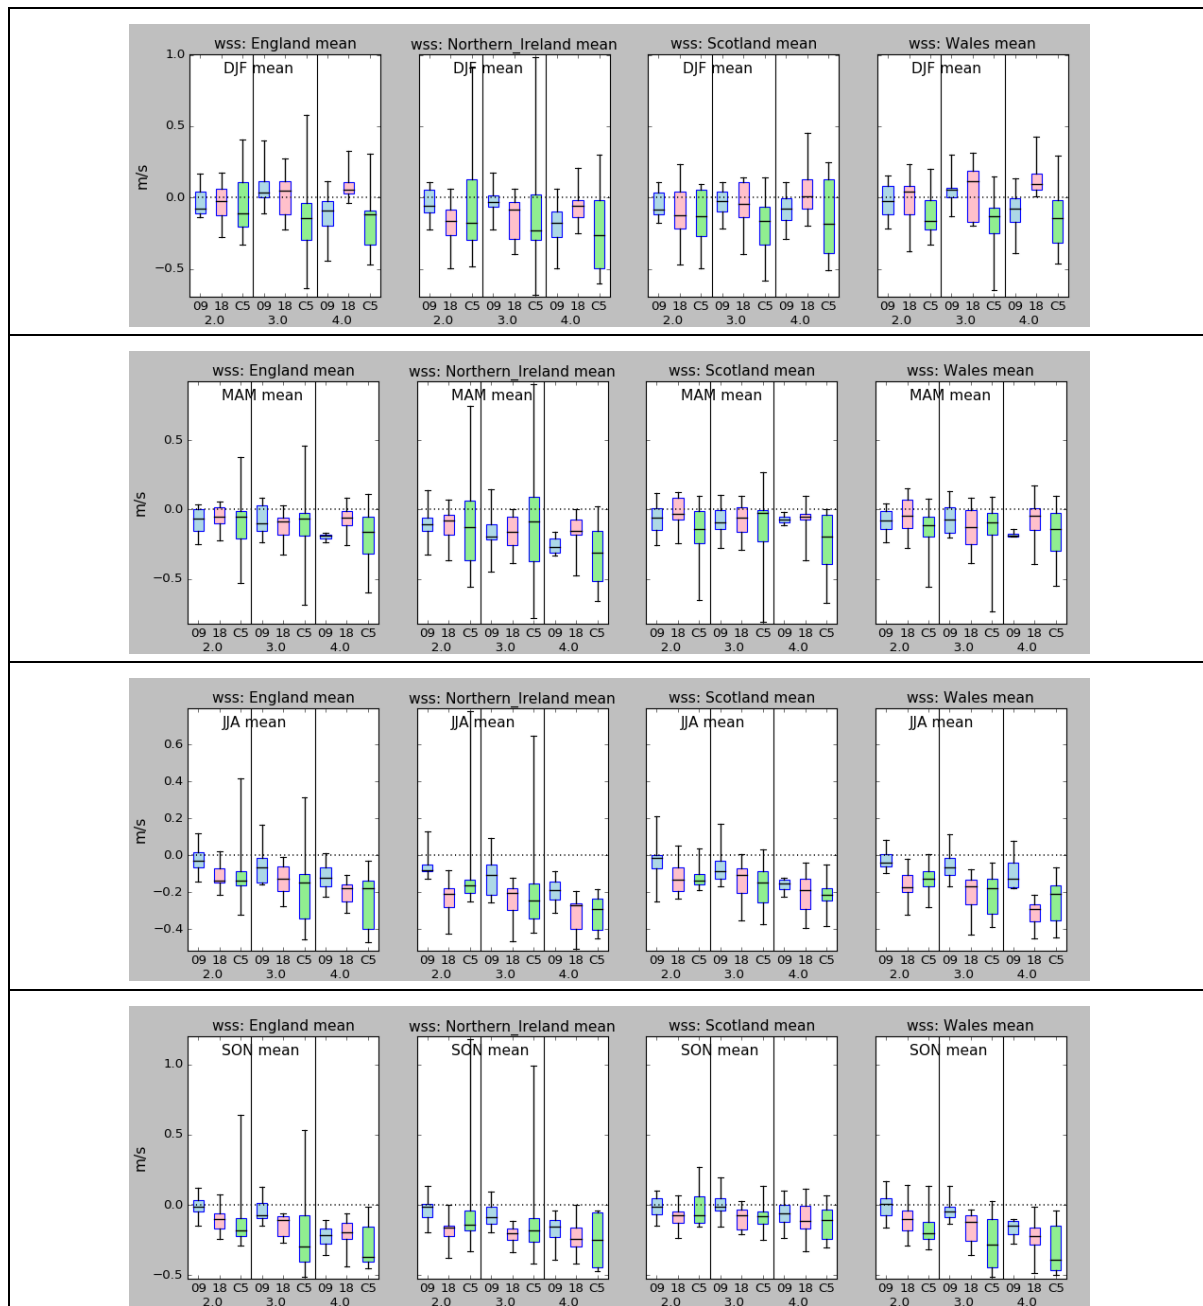

Another approach is to focus on whether the latest results from UKCP18 differ from UKCP09 in ways that are important for assessing climate risks. Johns (2021) documents a comprehensive comparison, and some specific highlights are shown here.

In the context of future renewable energy supplies, changes in near surface winds and in sunshine hours will be important climatic impact drivers, as will changes in peak demand driven for example by clustering of hot days. Figure 1.42 shows projected changes in near surface (10-metre) winds for each season and for each UK nation, from the UKCP09 regional model ensemble (blue), the UKCP18 regional model (pink) and the CMIP5 global model ensemble (green).

---

<sup>12</sup> Cooling Degree Days (CDD) are calculated as the product of the number of days above 22°C and the number of degrees above 22°C on each day where that threshold is exceeded.

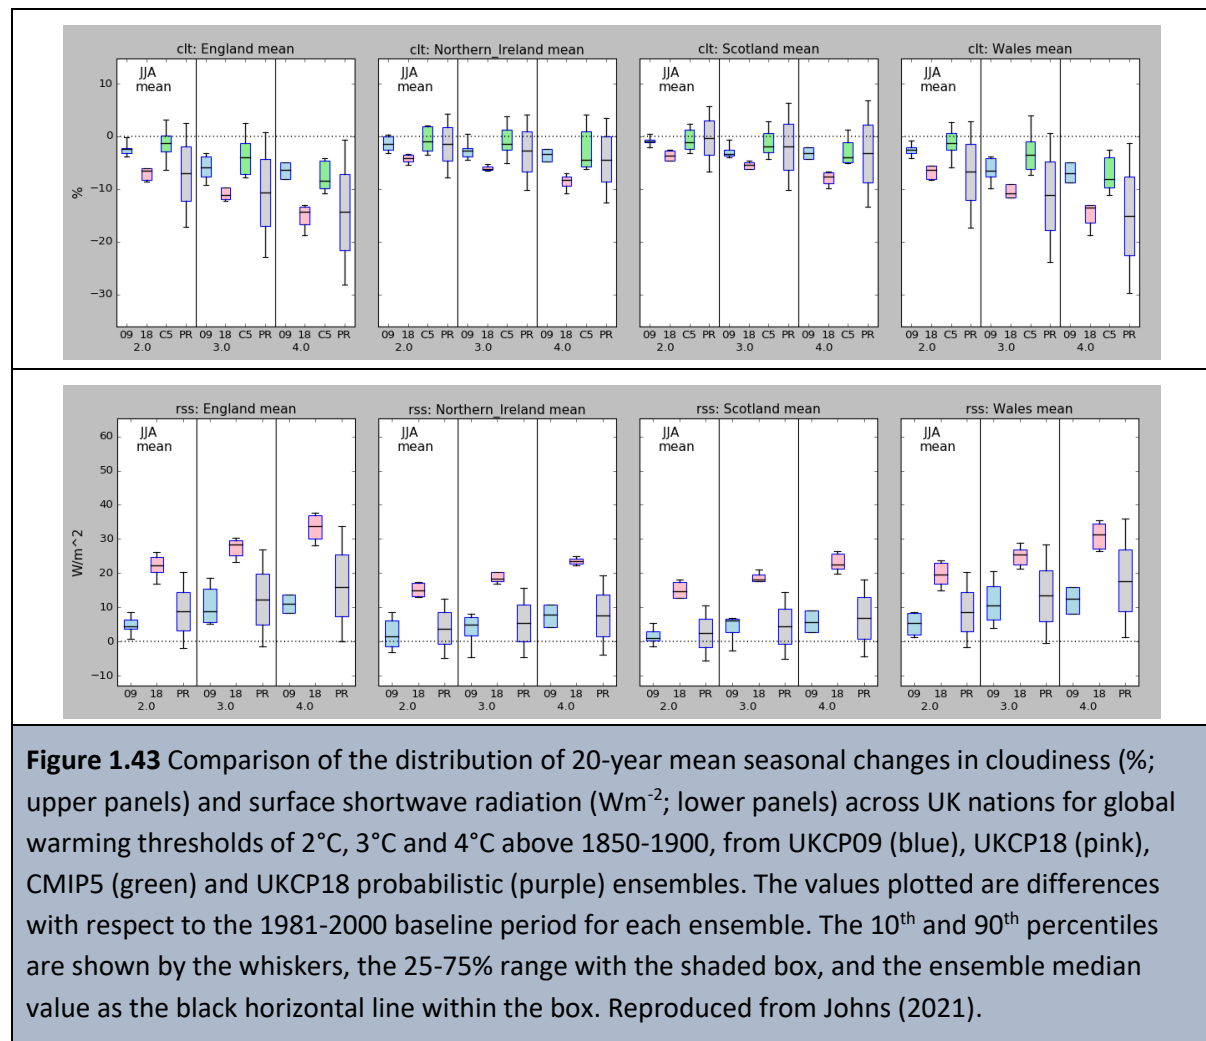

**Figure 1.42** Comparison of the distribution of 20-year mean seasonal changes in near-surface (10 meter) wind speeds (m/s) across UK nations for global warming thresholds of 2°C, 3°C and 4°C above 1850-1900, from UKCP09 (blue), UKCP18 (pink) and CMIP5 (green). The values plotted are differences with respect to the 1981-2000 baseline period for each ensemble. The 10<sup>th</sup> and 90<sup>th</sup> percentiles are shown by the whiskers, the 25-75% range with the shaded box, and the ensemble median value as the black horizontal line within the box. Reproduced from Johns (2021)

In winter, there is a large spread and no clear signal across the three sources of evidence that would imply robust changes in wind energy supply. In the other seasons there is a consistent, but small, signal of weaker winds, except in summer where the declines are larger, especially in the UKCP18 results. This is consistent with the increased prevalence of summer blocking noted earlier in Section 1.5.4.

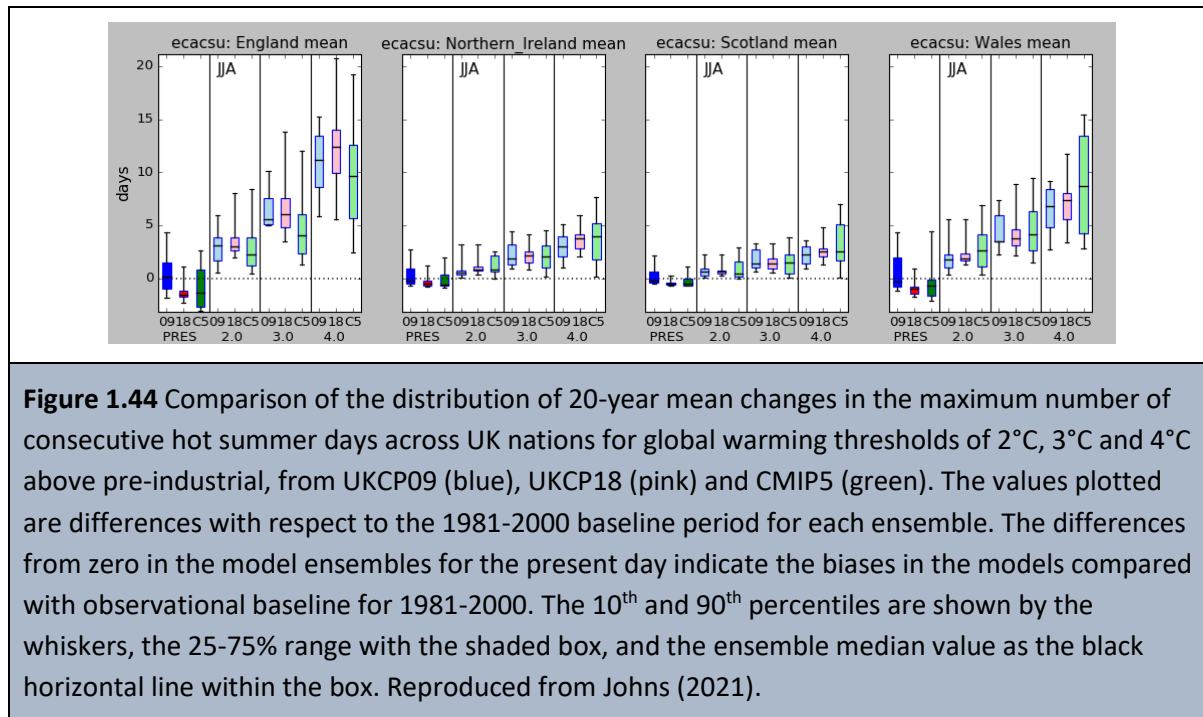

The availability of solar energy depends strongly on cloudiness and how this may be affected by changes in the UK's weather patterns. This is particularly important in summer when the availability of solar energy is at its peak. Figure 1.43 shows a comparison of projected summer changes in the cloudiness (upper panel) and surface shortwave energy (lower panel) for UK nations, from the various sources of evidence available to CCRA3. As well as the UKCP09, UKCP18 and CMIP5 ensembles, Figure 1.43 also shows the new probabilistic global projections (purple), which along with CMIP5 also include HadGEM3 results.

As in previous assessments, there is a decrease in summer cloudiness for all nations, which becomes more marked for higher warming levels. However, UKCP18 shows more substantial reductions in cloudiness for England and Wales, consistent with more dry summer blocking events, as documented in Section 1.5.4. As expected from the greater reductions in cloudiness in UKCP18, the surface shortwave radiation increases for all UK nations, increasing by as much as  $30\text{Wm}^{-2}$ .

Another aspect of electricity supply is its resilience to periods of high demand. As the UK moves to milder winters but hotter summers, some of the peak demand may occur in the summer months associated with prolonged spells of hot weather and an increased demand for air conditioning. One way to assess this risk is to consider the clustering of hot days. Figure 1.44 shows the changes in the

maximum number of consecutive hot summer days, defined as days where the maximum temperature exceeds 25°C. The length of these hot spells increases systematically for all nations as global warming levels increase. For England and Wales hot spells may increase in length by as much as 15-20 days. When these results are compared with the current duration of heatwaves (see Figure 1.10), it suggests that England and Wales may be exposed to very long spells of hot weather.

The results shown in Figures 1.42 to 1.44 may imply that earlier assessments of seasonal changes in the UK's energy needs are largely unchanged between UKCP09 and UKCP18 except for summer. UKCP18 projects that future summers could be drier and hotter, which could imply increased demand for air conditioning, especially in south-east England (see Cooling Degree Days (CDD) in Figure 1.41).

As the UK warms, drought may become an increasing risk, especially with hotter, drier summers. This has been analysed by Hanlon *et al.* (2021a) using a simple Drought Severity Index (DSI). The DSI is a rainfall-based drought index expressed in terms of the n-month accumulated precipitation deficit as a percentage of the mean annual rainfall of the location. The DSI has been computed for 3-month, 6-month, 12-month and 36-month periods in order to cover timescales relevant to meteorological, agricultural and hydrological droughts. Meteorological droughts are defined essentially on the basis of short-term rainfall deficiencies, whereas agricultural droughts relate to the gradual depletion of soil water during the growing season, and hydrological droughts are accumulated shortfalls in runoff or aquifer charge over longer periods.

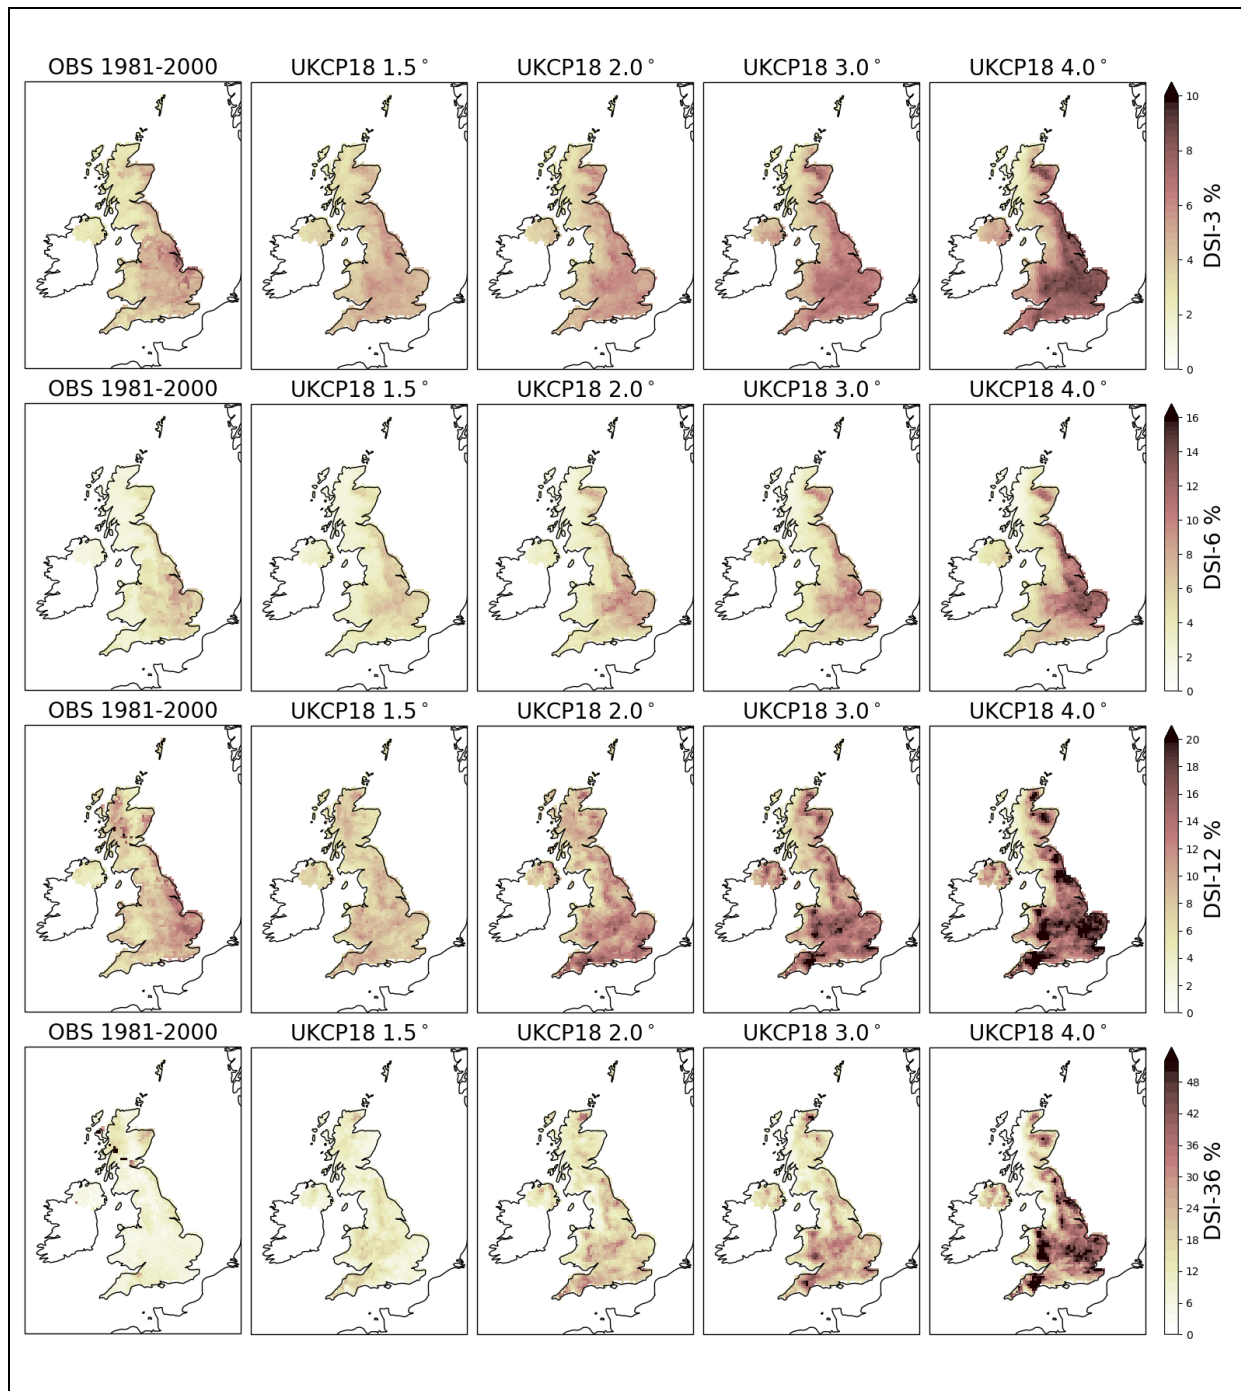

Figure 1.45 shows the DSI for a range of durations from 3 to 36 months across various global warming thresholds, where the drought severity is expressed as the % shortfall in the n-month accumulated precipitation with respect to the climatological annual average for the specific global warming level. The results show that essentially for all drought periods, their severity increases with

the warming level. This is particularly the case for the longer period, hydrological droughts where the changes in the accumulated deficits can be substantial. This would imply severe pressures on water resources and the sustainability of agriculture.

In summary, this additional analysis, using the framework of global warming levels rather than time horizons, has demonstrated how climatic impact drivers, directly relevant to specific sectors, are likely to change. It has also highlighted where there are significant differences in the evidence base given by UKCP18 from that used in earlier CCRA's. Key points include:

- All parts of the UK will continue to experience a steady reduction in frost days as global warming increases, implying a general trend towards fewer cold weather-related impacts in the long-term average, although some years will still see similar numbers of frost days and cold-related impacts as in recent years.
- A significant reduction in the number of icing days across the UK with increases in global warming, with fewer severe cold weather impacts and potentially less transport disruption. Most of the reductions in icing days occur up to a global warming of 3°C with little further reduction from 3 to 4°C.
- An increase in the incidence of high summer daytime temperatures throughout the UK. In the future, Scotland and Northern Ireland could start to see high summer temperatures similar to those of England and Wales currently.
- A rapid rise in the frequency of 'summer days' and 'tropical nights'. Since most of these events will cluster during the summer months, adaptation to cope with far hotter summers than we are currently experiencing will become important, with cities, especially London, facing the greatest challenge.
- A reduction in heating degree days and an increase in cooling degree days is projected for all global warming levels. Over South East England, cooling degree days increase 6-fold for a global warming of 4°C
- A clear signal in UKCP18 of decreasing total cloud amount and increasing surface shortwave radiation in summer, especially in southern England, is likely associated with more positive SNAO summers and associated reductions in rainfall and cloudiness. There are also more significant reductions in summer near-surface winds in UKCP18. On the other hand, there is no consistent signal for reductions in windiness in winter.
- Meteorological, agricultural and hydrological droughts are expected to become more severe with implications for water resource management.

**Figure 1.45** Maps of median values of the Drought Severity Index (DSI) computed for 3 (DSI-3), 6 (DSI-6), 12 (DSI-12) and 36 (DSI-36) month periods. The DSI is the n-month accumulated shortfall expressed as a % of the annual average precipitation. Observations for 1981-2000 and the model projections at 1.5°C, 2°C and 4°C of global mean warming above 1850-1900. Values at future warming levels are calculated as the 21-year average indices centred on the year each warming level is projected to be reached. Reproduced from Hanlon *et al.* (2021a).

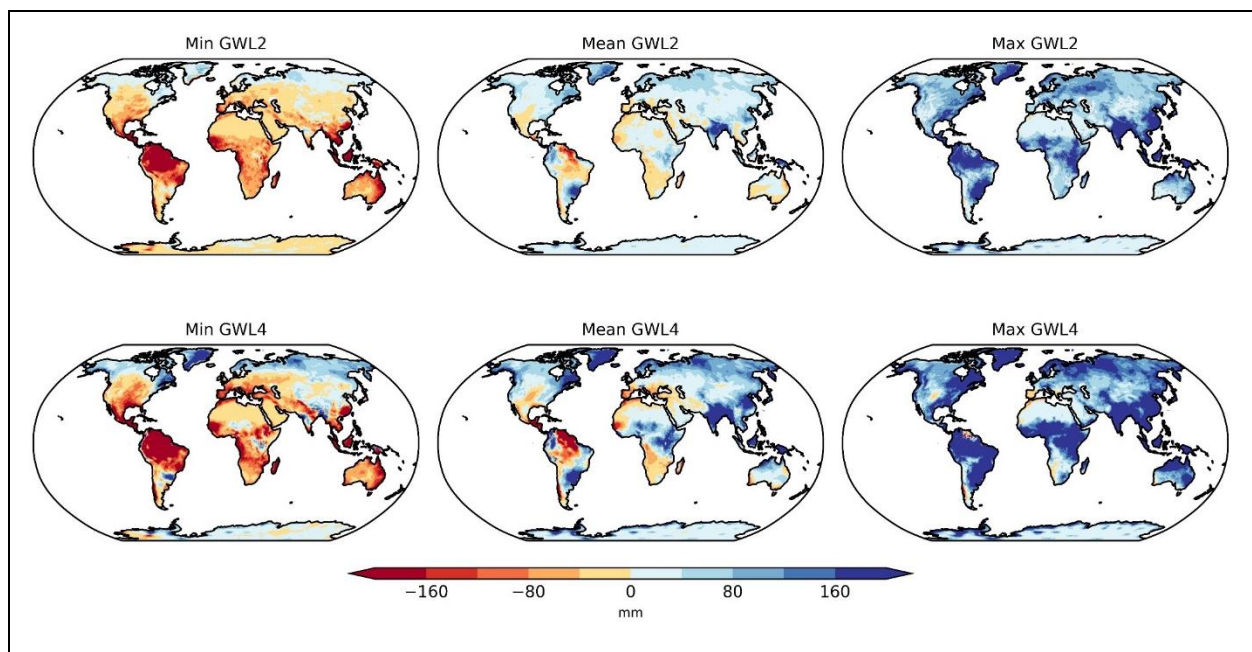

## 1.7 Projected climate changes worldwide

The UK is sensitive to climate change beyond its borders and so global projections are helpful for thinking about the international dimensions of climate risk to the UK (such as disrupted food supply chains). Extensive information on projected global patterns of climate change is presented in IPCC Assessment Reports and Special Reports (see <https://www.ipcc.ch>). While these include comprehensive assessments of uncertainties in regional climate changes, these are typically presented in terms of the average changes from multiple models, along with information on the degree of consensus between models.

For risk assessments, however, it can be useful to provide clear information on ranges of projected changes, hence the presentation style adopted in the UKCP09 and UKCP18 probabilistic projections for the UK (Murphy *et al.*, 2009; Murphy *et al.*, 2018). This can be particularly important for projected changes in precipitation, which can often differ in sign between models or realisations. Since the average change can be substantially smaller in magnitude than for individual realisations, this can fail to provide adequate information on the risk of larger potential changes.

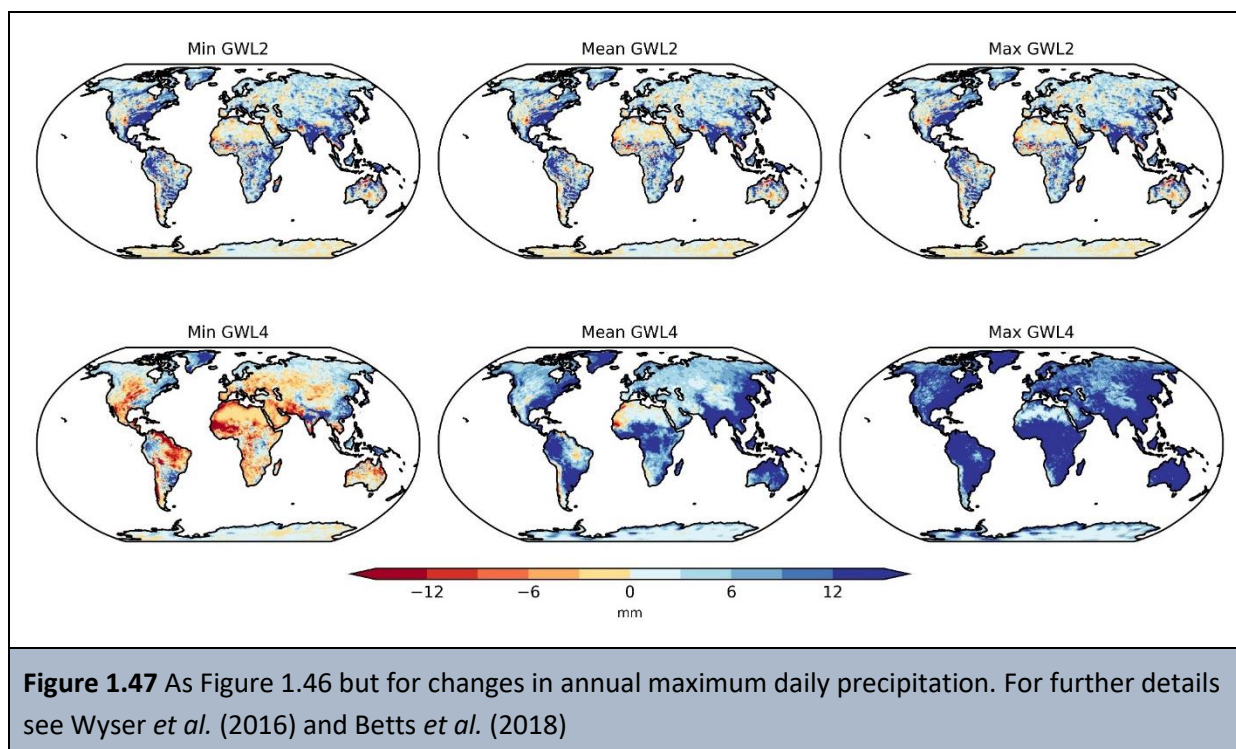

Here, projected global patterns of future changes in selected indices of precipitation are presented from an ensemble based on two different atmosphere models driven by sea surface temperatures from a selection of CMIP5 models, to illustrate the altered character of worldwide precipitation at 2°C and 4°C global warming, showing ranges of outcomes following the style of UKCP09 and UKCP18.

Annual total precipitation is projected to change in all land regions of the world (Figure 1.46). In this ensemble, increased precipitation across the Arctic region is consistently projected by all members at both GWLs. In all other regions, there is no consensus on the sign of the change across the range of outcomes from the driest to the wettest at both GWLs. However, the pattern of changes stays largely the same across GWLs and the magnitude of the changes is generally larger at 4°C global warming compared to 2°C.

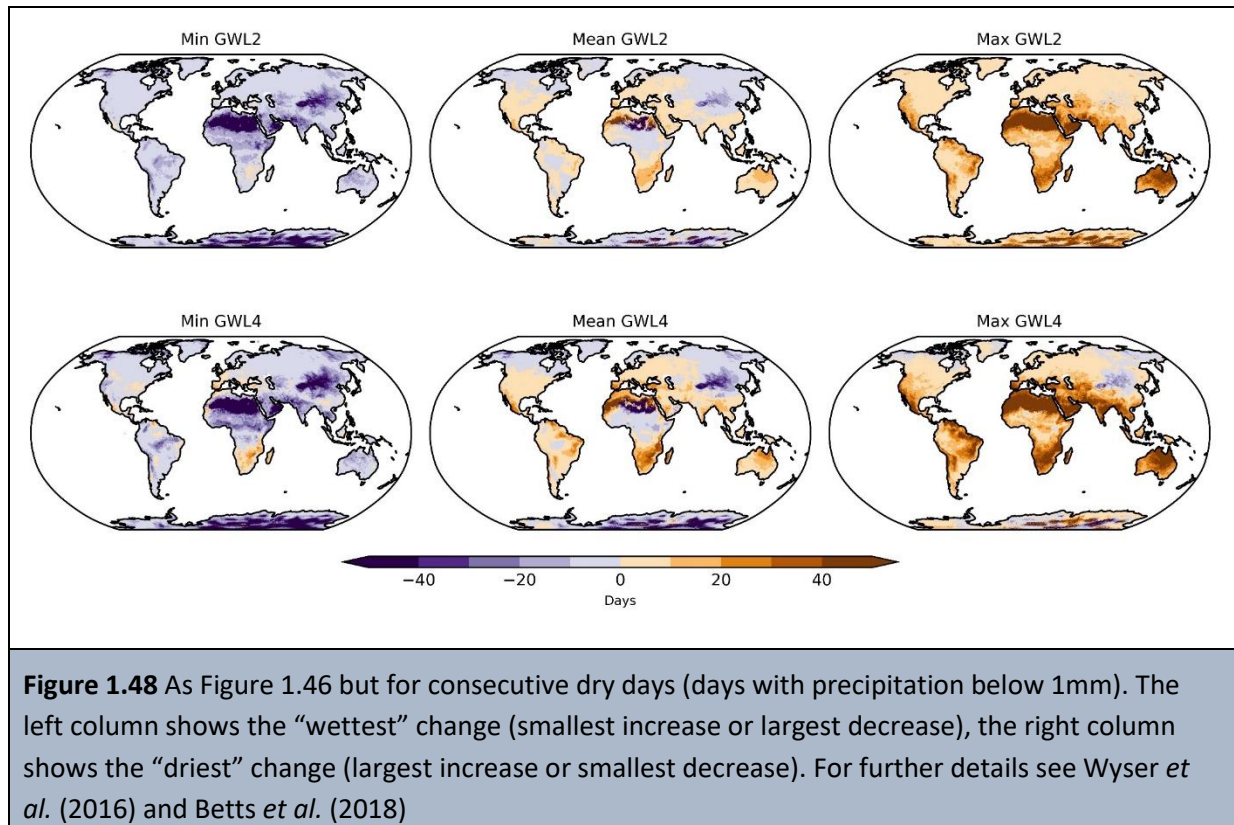

**Figure 1.46** Projected changes in 20-year mean annual total precipitation (mm) relative to 1981-2010, at global warming levels (GWLs) of 2°C (top row) and 4°C (bottom row) relative to preindustrial, from an ensemble of simulations with the atmosphere components of the HadGEM3-GC2 and EC-Earth vn3.1 climate models; these are driven by patterns of sea surface temperature change from a subset of the CMIP5 projections using the RCP8.5 concentration pathway. The centre column shows the multi-model mean for each grid point, the left column shows the “driest” change (largest decrease or smallest increase) at each grid point, and the right column shows the “wettest” change (smallest decrease or largest increase). For further details see Wyser *et al.* (2016) and Betts *et al.* (2018)

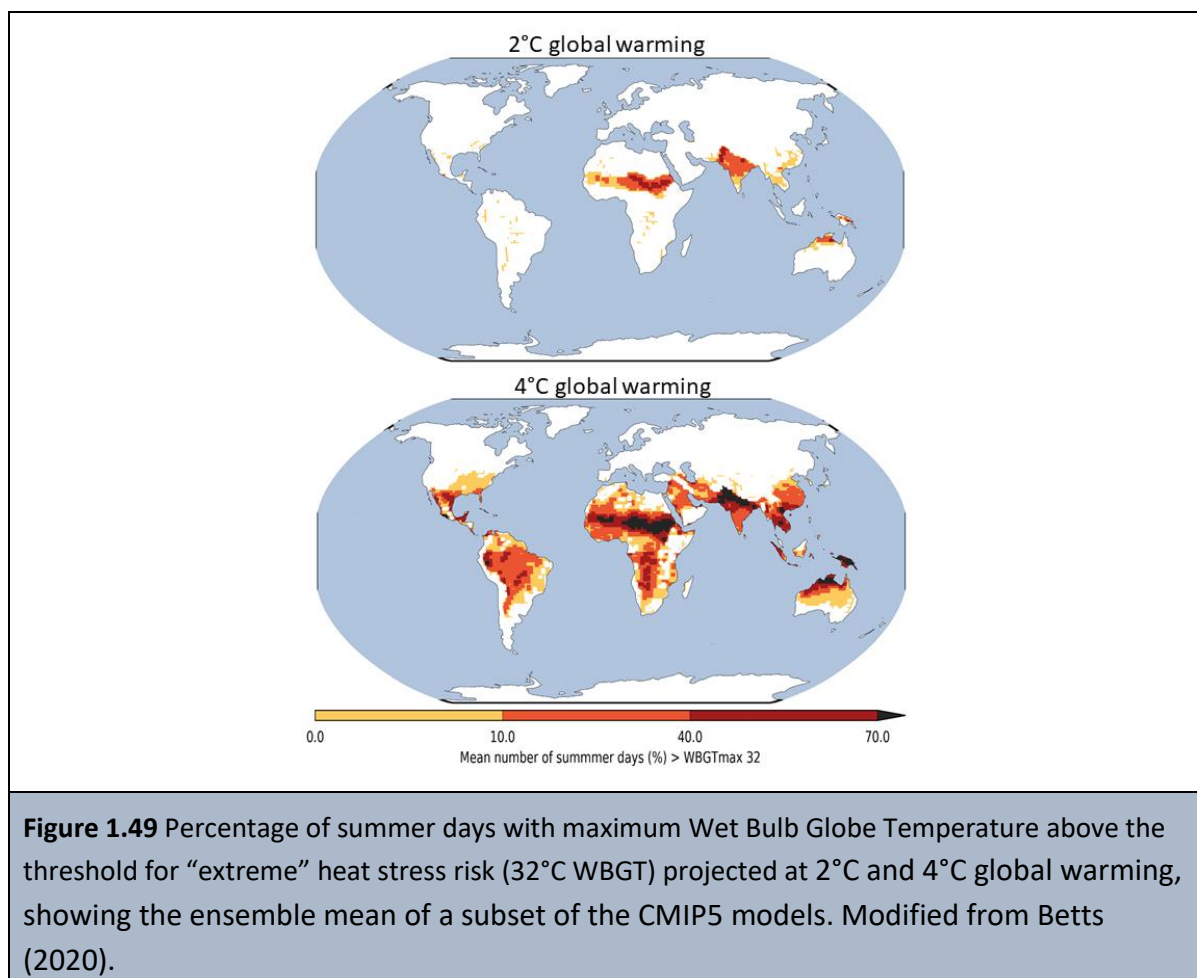

Heavy precipitation shows a more consistent increase at 2°C global warming, but uncertainty in the sign of change becomes more widespread at 4°C warming (Figure 1.47). Importantly, the largest projected increases are generally substantially larger than the mean of the projections, underlining the importance of considering the range of projected changes for risk assessments.

The length of dry spells is also projected to change in different ways in different regions worldwide, again with disagreements in the direction of change among the ensemble in many regions (Figure 1.48). At 4°C global warming, there is a consensus across all models on dry spells increasing by 10 days or more across large parts of southern Africa, the Iberian Peninsula and a number of small regions, and a consensus on shorter dry spells in eastern central Asia and some Arctic lands, but in most regions the ensemble projects that dry spells could either increase or decrease. In some regions, including highly populated areas such as the Indian subcontinent, the maximum projected 20-year mean increase is over 40 days per year.

The most extreme high temperatures are projected to occur in regions that are already hot. Human heat stress depend on humidity as well as temperature, and for industry uses is routinely quantified with Wet Bulb Globe Temperature (WBGT) using temperature, humidity and solar radiation. WBGT of 32°C is classified as “extreme risk” of heat stress and is rarely seen in the current global climate. Figure 1.49 shows the percentage of summer days with maximum WBGT above 32°C projected for GWLs of 2°C and 4°C, using the mean of several simulations with a subset of the CMIP5 models. Extreme heat stress conditions are projected for more than 10% of summer days in most tropical regions and many parts of the sub-tropics at 4°C global warming, and many of the more highly-populated areas of the world for more than 40% of summer days.

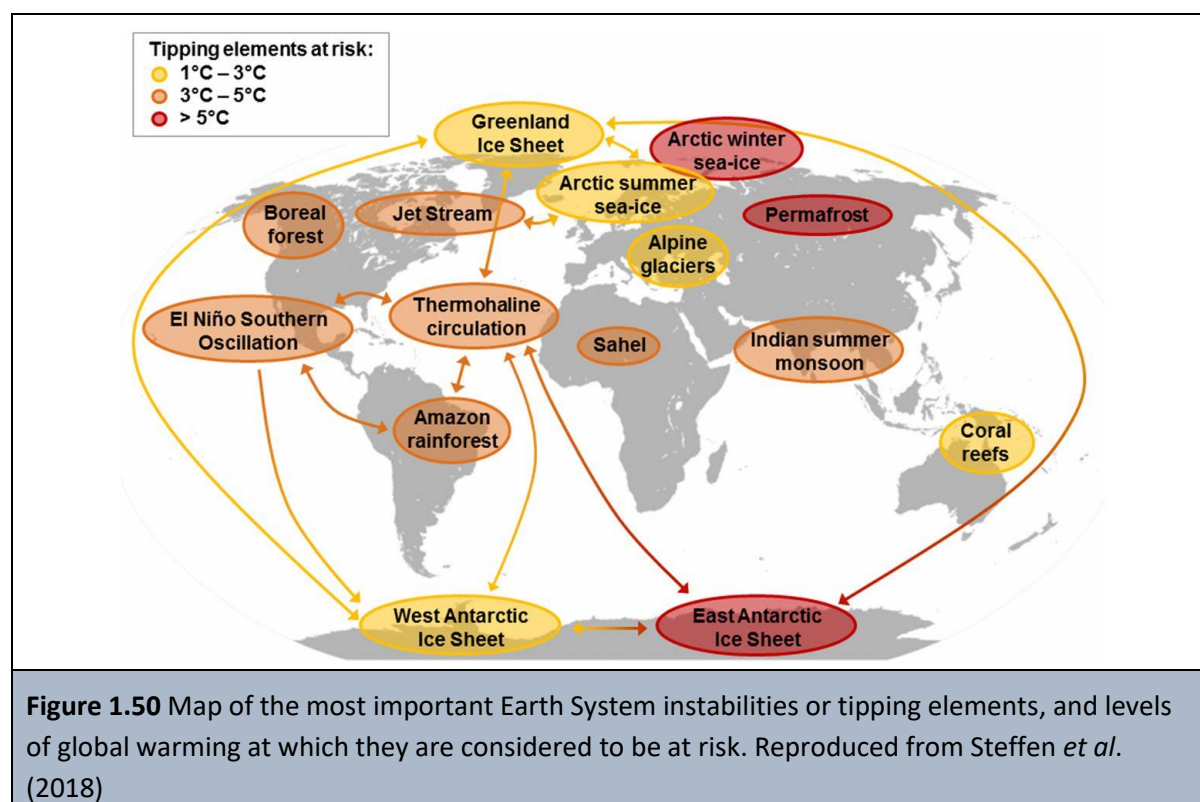

## 1.8 Earth System Instabilities – Potential risks of rapid and/or irreversible changes

Earth System Instabilities (often known as tipping points) describe accelerating, rapid or irreversible changes within the Earth System in response to external forcing. These can involve the physical climate system (e.g. ice sheets), terrestrial carbon cycles and ocean biogeochemistry, they can operate on a range of timescales and can be manifest at global or regional levels. Some are regarded as reversible, but some may persist for centuries or longer. Recent work (e.g. Steffen *et al.*, 2018) has emphasised the links between various Earth System instabilities and considered the risk that self-reinforcing feedbacks, often referred to as tipping cascades, could push the Earth System toward a planetary threshold that, if crossed, could prevent stabilization of the climate at intermediate temperature rises even as human emissions are reduced.

Figure 1.50 provides a useful summary of our current understanding of potential candidates that may exhibit behaviours that could drive the system to more extreme climate states. A report on ‘Effect of Potential Climate Tipping Points on UK Impacts’ has been produced for CCRA3 (Hanlon *et al.*, 2021b).

For the purposes of CCRA3, three classes of Earth system instabilities are considered. Firstly, those that could affect the UK directly through changes in our regional weather and climate without necessarily changing the level of global warming. Secondly, those involving changes in land ice, affecting sea level rise impacts in the UK and worldwide. Thirdly, those related to feedbacks involving carbon or other biogeochemical cycles that could increase the likelihood of higher levels of global radiative forcing, and hence increase the likelihood of large regional climate changes in the UK.

### 1.8.1 Weakening or collapse of the Atlantic Meridional Overturning Circulation

The UK's weather and climate are fundamentally controlled by the Atlantic Meridional Overturning Circulation (AMOC), and especially by the warm, returning branch, the Gulf Stream. Although shutdown of the AMOC is considered very unlikely this century, it remains a plausible outcome in the next century (IPCC, 2019). However, significant weakening of the AMOC is considered likely and the latest results (Weijer *et al.*, 2020) suggest that the CMIP6 models project stronger weakening than in IPCC AR5, with a possible AMOC decline between 34% and 45% by 2100. These projected declines are already represented in the UKCP18 results.

Weakening of the AMOC would lead to a cooling effect on the UK's climate, although not enough to offset anthropogenic warming. However, the effects of AMOC weakening on specific aspects of the UK's weather and climate may act to exacerbate the trends due to global warming documented in Section 1.5. These include shifts in rainfall patterns (including summer drying), increases in winter

storminess, and further rises in sea level due to changes in the ocean density and circulation (e.g., Vellinga and Wood, 2008).

Ritchie *et al.* (2020) have considered the impacts on UK land use and food production of an extreme scenario in which there is a rapid weakening and AMOC collapse between 2030 and 2050. Figure 1.51 shows the changes in temperature and precipitation through the 21<sup>st</sup> century, without and with AMOC collapse, where the climate change signal is taken from UKCP09 regional model projections using the SRES-A1B emission scenario (Nakićenović, N. *et al.*, 2000).

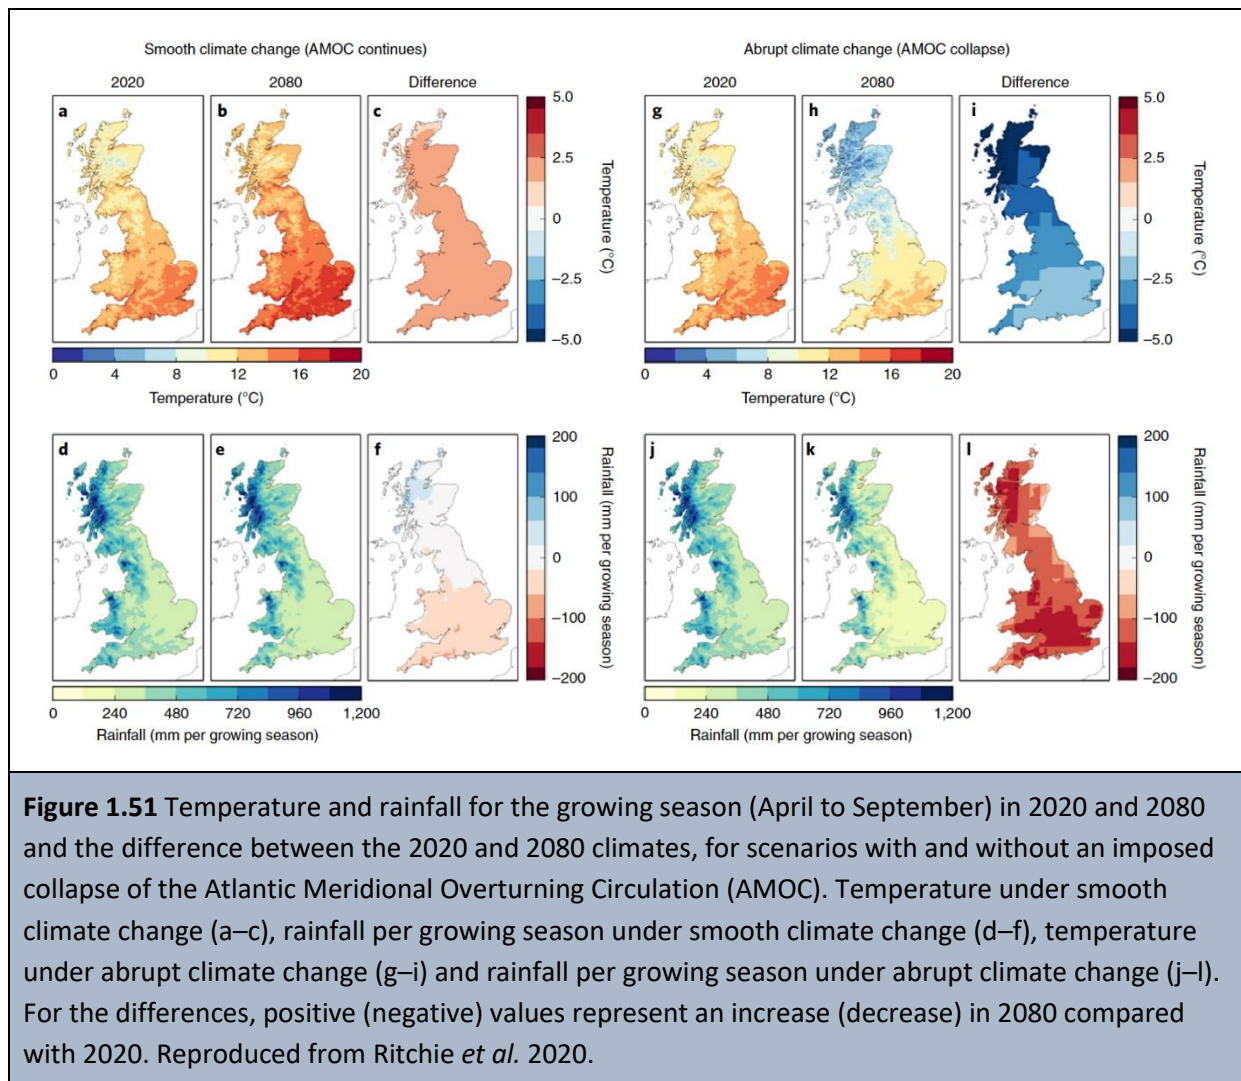

Figure 1.51 provides a striking demonstration of the impacts of AMOC collapse on growing season conditions in the context of ongoing climate change. The impacts are likely to include widespread cessation of arable farming, with losses of agricultural output that are an order of magnitude larger than the impacts of climate change without an AMOC collapse.

### 1.8.2 Changes in the behaviour of the North Atlantic Jet Stream

As already discussed, the UK's weather and climate are strongly influenced by the position and strength of the North Atlantic jet stream which in turn can alter the frequency and/or magnitude of high-impact or extreme weather events. Recent extreme events, involving winter flooding and summer heatwaves, have led to questions around whether the behaviour of the jet stream is changing, with more instances of major meanders north and south, and more stalling of these meanders. Meanders in the jet are often referred to as Rossby or planetary waves and we know that slow moving, amplified Rossby waves favour the occurrence of extreme weather conditions over the UK. For example, extended periods of wet or dry weather, such as winter 2013/14 and spring 2020, correspond to a jetstream meander stalling and becoming locked in one position.

It has been postulated that the amplified warming of the Arctic with the associated loss of Arctic sea ice may be weakening the jet stream and hence making it more susceptible to amplified and persistent wave anomalies (e.g., Francis and Vavrus, 2012). However, evidence to support this hypothesis has not yet been forthcoming, but it has raised interesting questions over how the jet stream might respond to warming. We know that there is a link between the strength of the jet stream and its meanders north and south (e.g., Woollings *et al.*, 2018), in which a weaker jet stream favours more meanders, and, relatedly, more blocking events and accompanying high-impact weather. However, Woollings *et al.* (2018) have shown that North Atlantic jet variability is modulated on multi-decadal time scales, with decades of a strong, steady jet being interspersed with decades of a weak, variable jet.

There is as yet no robust evidence that the North Atlantic Jet Stream is changing. Furthermore, the future behaviour of the North Atlantic Jet stream is not understood, and yet could have profound implications for the UK's weather and climate. The potential exists for significant changes in its preferred location, in its variability and in its propensity for slow moving, or even stationary, amplified Rossby waves. There is an urgent need to fill this knowledge gap.

### 1.8.3 Accelerated loss of Antarctic and Greenland ice sheets

Sea level rise has two major contributors – thermal expansion of the oceans as they warm (remembering that the oceans take up around 90% of the additional energy trapped in the planet), and the accumulation of ocean water mass as ice sheets and glaciers melt. Today mass accumulation dominates global sea level rise accounting for about two-thirds of the total. This is primarily due to accelerating loss of mass from the major ice sheets of Greenland and Antarctica.

The main mechanism for Greenland ice melt is changes in surface mass balance, where ice melts faster than snow can accumulate. This mechanism occurs at a steady rate and is not likely to exhibit accelerating or abrupt changes. The IPCC SROCC (2019) estimates that the complete loss of Greenland ice would contribute around 7m to global sea level rise, but this would take more than 1000 years. Sea level rise due to Greenland ice melt during the 21st century would be closer to 10s of centimetres.

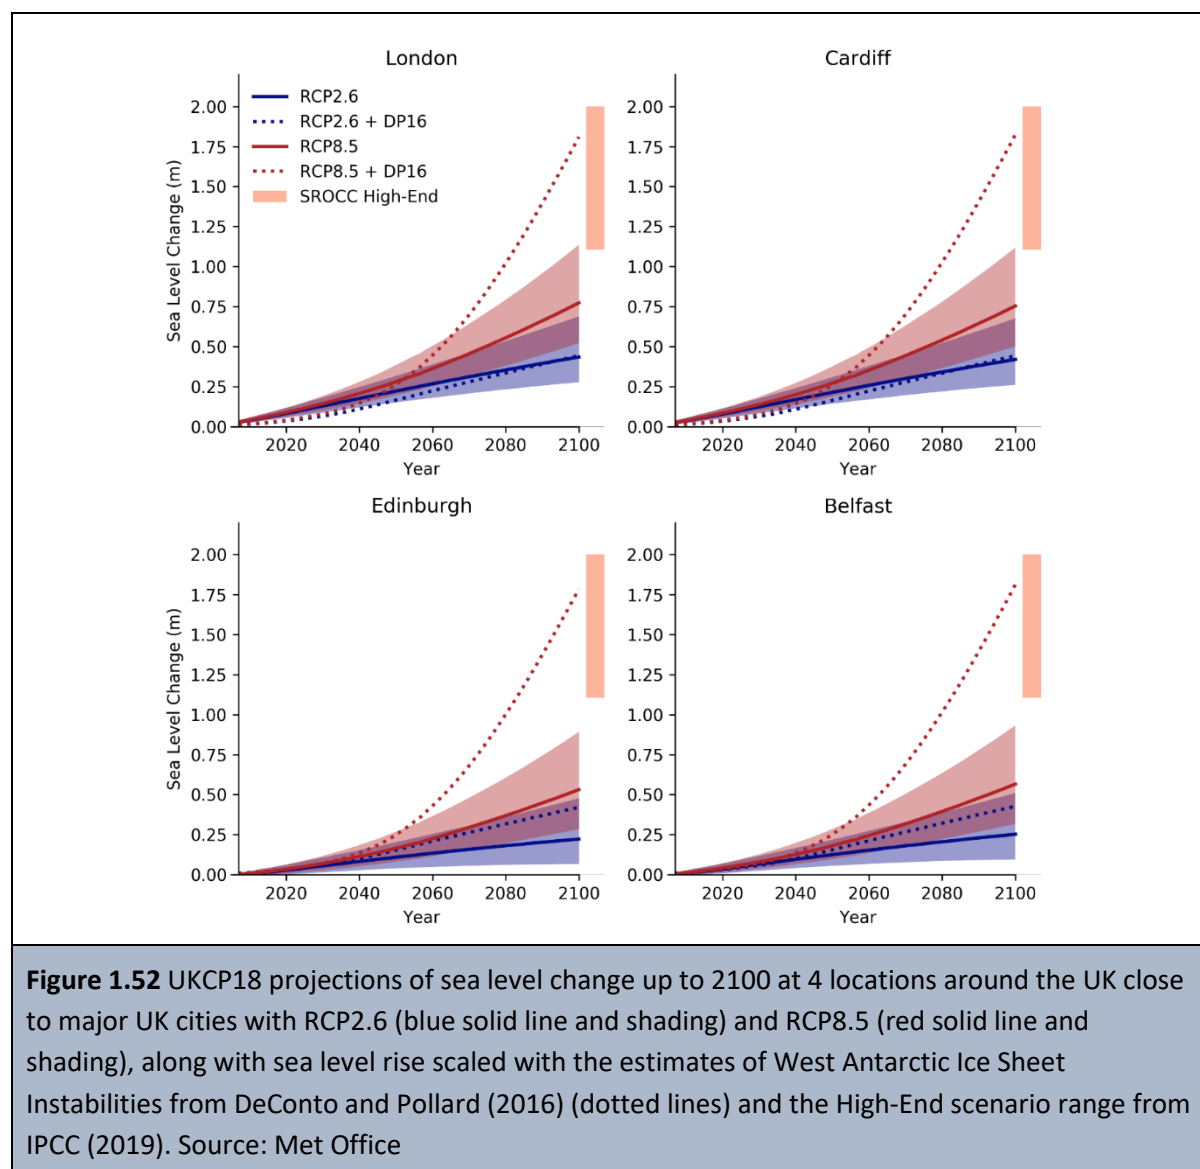

The main risk of abrupt change comes from West Antarctica, which is losing ice mass primarily due to ice flow processes but could start losing ice more rapidly from accelerating instability processes.

Recent advances have highlighted the potential for collapse of the West Antarctic Ice Sheet and consequent acceleration in the rate of global sea level rise. This is a predominantly marine-based ice sheet, where ice mass input to the ocean is governed primarily by ice flow processes rather than the surface mass balance that dominates for the East Antarctic Ice Sheet.

There are indications that collapse of the West Antarctic Ice Sheet could already be underway, through a positive feedback known as 'Marine Ice Sheet Instability' in which the ice sheet separates from its grounding line and floats free where it can melt more rapidly (e.g., Rignot *et al.*, 2014). Recently, a second potential positive feedback on ice loss from West Antarctica has been proposed called 'Marine Ice Cliff Instability' (Pollard *et al.*, 2015). This feedback would be triggered by disintegration of the floating ice shelves around Antarctica; wherever these leave behind tall coastal ice cliffs that would be structurally unstable, they may collapse entirely leaving behind further unstable cliffs. This could lead to self-sustaining ice losses and associated global sea level rise of order 1m by 2100 if the feedback were rapid and widespread (e.g. DeConto and Pollard, 2016).

Figure 1.52 shows the impact of Marine Ice Cliff Instability on sea level rise for selected UK cities based on the simulations of DeConto and Pollard (2016) compared with the UKCP18 projections (Palmer *et al.*, 2018), along with the high-end assessments from IPCC (2019). These assessments show that the UK should be prepared for up to 2m sea level rise by 2100 in the event of accelerated Antarctic melting, which suggests a similar upper bound to the UKCP09 H++ scenario (1.9m) for the UK.

### 1.8.4 Permafrost thawing and additional carbon emissions

Permafrost is a mixture of soil, rocks and ice which remains permanently frozen throughout the year. Carbon stored in the permafrost is relatively inert as temperatures are too cold for much microbial activity to occur. A warming climate can induce environmental changes that accelerate the microbial breakdown of organic carbon and the release of the greenhouse gases, carbon dioxide and methane. Methane is of particular concern because although its lifetime is much shorter, it is a far more potent greenhouse gas than carbon dioxide. The addition of these greenhouse gases to the atmosphere would increase global warming and lead to further thaw, an amplifying process referred to as the “permafrost carbon feedback”.

Should the permafrost thaw, the carbon would not necessarily be released into the atmosphere immediately. The timescales of soil carbon decomposition are much slower than the projected rate of permafrost thaw. In addition, there is likely to be enhanced vegetation growth caused by warmer

temperatures with increased CO<sub>2</sub> uptake. Schuur *et al.* (2015) estimate that for a high emission scenario, carbon release from permafrost is projected to be in the range 37–174 Pg of carbon by 2100, which gives a possible range of additional global warming of 0.13–0.27°C by 2100 and up to 0.42°C by 2300.

However, recent research has highlighted the importance of abrupt thawing events that could release far more carbon than a gradual thawing assessed so far (Turetsky *et al.*, 2020). Across the Arctic and Boreal regions, permafrost is collapsing suddenly as pockets of ice within it melt. Instead of a few centimetres of soil thawing each year, several metres of soil can become destabilized within days or weeks. The land can sink and be inundated by swelling lakes and wetlands.

Abrupt thaw would probably occur in up to 20% of the permafrost zone (Olefeldt *et al.*, 2016) but could contribute half of permafrost carbon through collapsing ground, rapid erosion and landslides. Under a high emission scenario Turetsky *et al.* (2020) estimate that emissions across 2.5 million km<sup>2</sup> of abrupt thaw could provide a similar climate feedback as gradual thaw emissions from the entire 18 million km<sup>2</sup> permafrost region. After considering abrupt thaw stabilization, lake drainage and soil carbon uptake by vegetation regrowth, they conclude that models considering only gradual permafrost thaw are substantially underestimating carbon emissions from thawing permafrost.

The impact of permafrost thaw on the UK would be an indirect one, associated with more rapid global warming and subsequent changes to our weather and climate. Also, the release of additional greenhouse gases would reduce the allowable carbon budget to keep within a certain level of global warming and hence is important for mitigation policies. For example, Gasser *et al.* (2018) compared the carbon budgets and targets of the Paris Agreement with carbon emissions from permafrost in an Earth system model. They concluded that permafrost thaw could use up 10-100% of the allowable carbon budget to stay within 1.5° C and up to 25% of the budget to stay within 2°C. Once emitted these additional carbon emissions would be irreversible for centuries.

### 1.8.5 Reduced carbon uptake by the biosphere

Land and ocean ecosystems act as natural buffers that limit the increase of CO<sub>2</sub> in the atmosphere by absorbing and sequestering nearly half of emitted CO<sub>2</sub>. As human emissions have continued to increase, this natural climate change mitigation has so far proportionally kept pace with emissions, with, for example, enhanced vegetation growth from CO<sub>2</sub> fertilisation.

It is expected that the ocean's ability to take up carbon will continue, although the oceans will become more acidic with consequences for marine organisms (IPCC, 2019). This may not be the case for the land carbon sink where the situation could deteriorate quite rapidly, as deforestation and changing climatic conditions affect the major forests of Amazonia and the northern hemisphere boreal regions.

The Amazon rainforest involves a symbiotic relationship between the trees and the hydrological cycle in which a significant fraction of the rainfall falling on the forest is recycled by the forest in a self-sustaining feedback loop. In recent decades, new forcing factors – deforestation, widespread use of fire to clear vegetation and climate change - have begun to break that loop. There is also evidence that the recent climate of Amazonia has been subject to large oscillations between severe droughts and floods (Yang *et al.*, 2018) that act to destabilise the forest system. The severity of the

droughts is part of an emerging picture of an increasingly extended dry season, potentially associated with the warming of the tropical North Atlantic and shifting circulation patterns, but also with deforestation.

All these factors have raised the question of how much would be required to degrade the symbiotic relationship between the forest and the hydrological cycle, to the point that Amazonia is unable to support rain forest ecosystems and lose its role as a robust and important sink of carbon. Lovejoy and Nobre (2018, 2019) have suggested that the negative synergies between deforestation, climate change and the widespread use of fire indicate a tipping point for the Amazon system at 20-25% deforestation. Current estimates of deforestation are around 17% for the whole of Amazonia so the forest system is already close to that suggested tipping point. The loss of forest would lead to substantial losses of biodiversity and carbon with far-reaching ramifications.

The boreal forests of the northern hemisphere are also at risk from climate change. These forests store 30-40% of all land-based carbon in the world, and most of that carbon is found in the soils. High latitude warming is projected to increase dieback and disturbance in boreal forests, with increased prevalence of fires, pests and disease. All these factors could alter the structure, composition and functioning of the boreal forest systems. However, the impact on the climate system is expected to be less profound than for the Amazon rainforest, where most of the carbon is stored in the trees, and deforestation and climate change may lead to an abrupt collapse of the ecosystem.

Regarding UK impacts, the effects of forest loss would be indirect. The loss of forests would reduce the efficiency of terrestrial carbon sinks, leading to increased atmospheric concentrations and accelerated global warming. As with permafrost thaw, allowable carbon budgets to stay within specific levels of warming will be reduced with implications for mitigation.

## 1.9 Looking ahead to CCRA4

Important advances in climate science evidence have been made leading up to CCRA3 and during its production, particularly through UKCP18 and subsequent releases of further components of the UK Climate Projections. However, in many cases, the full range of evidence, especially from the regional and convection-permitting models, became available while the CCRA3 process was underway and hence in many cases could only be exploited in a limited way in the sectoral risk assessments. This is reflected in the assignment of confidence levels. One example is the use of threshold exceedance metrics with the convection-permitting model: information on these metrics is provided in Annex 2 for potential further use in research to inform CCRA4. Moreover, significant knowledge gaps still exist: key examples are summarised here, with suggestions for further research and development leading up to CCRA4.

### 1.9.1 Knowledge gaps in the scientific evidence

A theme of this chapter has been the importance of considering the volatility of the UK's weather and climate and how this may change in the future. Although some basic analysis has been done there needs to be a much greater emphasis on this in the future.

Weather regime analysis is one way forward (e.g. Neal *et al.*, 2016) which is already proving very valuable in operational forecasting and has been explored by De Luca *et al.* (2019) for interpreting future climate change in the CMIP5 projections. This needs to be repeated with the latest generation of models used in UKCP18 and IPCC AR6. Regime analysis has also been exploited for interpreting the incidence of extreme events which show clear evidence for preferred patterns (e.g. Darwish *et al.*, 2020).

Using weather regimes, insightful diagnostics on frequencies, residence times and transitions can be explored for the current climate and the links with modes of climate variability can be produced. These would form the basis for exploring how the UK's weather regimes may evolve with global warming and with changes in modes of climate variability. Regime analysis is already used very effectively in weather forecasting for identifying forthcoming risks across a range of sectors and this expertise may therefore be useful for assessing future levels of risk under climate change. Weather regimes may also act as useful vehicles for climate risk communication.

Linked to this, there needs to be a major focus on understanding the behaviour of the North Atlantic Jet Stream and how this will evolve in the future. This is vital for addressing current and future changes in storminess, atmospheric rivers, extreme winds, waves and coastal surges. As discussed in Section 1.8.2, this is a fundamental knowledge gap which needs to be filled before CCRA4.

### 1.9.2 Storylines and Scenarios

The conventional approach to representing uncertainty is through probabilistic approaches, based on ensembles of climate model simulations. One consequence of this is that the low-likelihood, high-impact events that may pose the greatest risks are difficult to isolate and factor into a risk assessment. An alternative approach is emerging called event-based storylines. Event-based storylines are physically self-consistent unfoldings of past events, or of plausible future events, with an emphasis on plausibility rather than probability (Shepherd *et al.*, 2018). This concept links directly to common practice in disaster risk management using “stress-testing” for emergency preparedness based on events that are conditional on specific (plausible) assumptions about the hazards and possible aspects of exposure and vulnerability of the affected human or ecological system. They are particularly applicable to extreme or unprecedented events whose probability cannot be quantified, but whose impacts could be profound.

There are several reasons why storylines may complement current, probabilistic-based methods:

- (i) Improving risk awareness by framing risk in an event-oriented rather than a probabilistic manner, which corresponds more directly to how people perceive and respond to risk.
- (ii) Strengthening decision-making by allowing one to work backwards from a particular vulnerability or decision point, combining climate change information with other relevant factors to address compound risk and develop appropriate stress tests.
- (iii) Emphasizing the plausibility rather than probability. This concept links directly to common practices in disaster risk management using “stress-testing” for emergency preparedness based on events that are conditional on specific, but plausible assumptions.

- (iv) Exploring the boundaries of plausibility, thereby guarding against false precision and surprise. Storylines also offer a powerful way of linking physical with human aspects of climate change.
- (v) Exploiting the latest generation of kilometre-scale climate models where the ensemble size may not be sufficient to define probabilities, but where the physical realism is such that plausible, and potentially unprecedented, extremes can be captured.

When co-developed by climate scientists and stakeholders, event-based storylines can provide a useful way of communicating and assessing climate-related risk in a specific decision-making context. Event-based storylines allow for conditional explanations, without full attribution of every causal factor, which is crucial when some aspects of the latter are complex and highly uncertain.

Strategic planning in government and business routinely makes use of scenarios as tools to inform thinking about future possibilities and how to manage them. Thus, scenarios are the obvious tool to describe future climate in ways that are relevant to decision-makers. Here, climate scenarios are defined as a discrete set of physically consistent and self-consistent storylines about the future, under a specified set of assumptions. The impacts and consequences of climate scenarios can be explored in considerable quantitative detail, using metrics that range from meteorological (e.g., rainfall rate) to those that are most decision relevant (e.g., flood level, numbers of people affected, and economic loss).

In summary, the development of CCRA3 has highlighted where significant gaps still exist in the climate science evidence which should be filled before CCRA4. Future options have been proposed which will improve end-to-end risk assessments and the uptake of the latest climate science, as well as enable stress-testing of future adaptation options to extreme or worst-case scenarios.

## Annex 1. Advances in climate modelling since CCRA2

### A1.1 Improvements to climate models

Since CCRA2, significant advances have been made in both global and regional modelling for weather and climate prediction. For climate science serving the UK, a new climate model, HadGEM3, is a key part of a comprehensive new set of UK climate projections (UKCP18) and other applications including global forecasts on timescales of months to a century. HadGEM3 features significant increases in horizontal and vertical resolution in the atmosphere and ocean, as well as improvements in model physics, giving notable reductions in a number of key systematic biases (Williams *et al.*, 2018). The atmosphere model resolution increased from 150km in the horizontal, as used for CMIP5 and IPCC AR5, to 60km, and from 38 to 85 levels in the vertical. The ocean resolution increased from 1° to 0.25° and from 40 to 75 levels.

These enhancements in resolution have delivered significant improvements in the structure of synoptic weather systems and ocean circulation, and in subseasonal and seasonal predictability for the UK, including precipitation (e.g., Scaife *et al.*, 2014). This is associated in part with much improved interactions between the stratosphere and troposphere with higher vertical resolution and better representation of the Gulf Stream with higher ocean resolution.

Analysis of the HadGEM3 perturbed parameter ensemble used in UKCP18 showed that, for all members, HadGEM3 out-performs the CMIP5 models across a wide range of climate variables (Figure A1.1 from UKCP18 Land projections: Science Report).

Another advance since CCRA2 has been the creation of a new ensemble of regional climate simulations based on the variants of HadGEM3 used in the perturbed parameter ensemble and driven by boundary conditions from the equivalent global model. So, the regional simulations have also benefited from the improvements in the North Atlantic weather and climate variability in HadGEM3.

The regional model uses a higher resolution of 12km compared with the earlier CORDEX and UKCP09 regional simulations at 25km and gives better representations of the UK landscape and its associated local meteorology, especially in mountainous and coastal areas. Variability in precipitation is higher than in the global model, in better agreement with the observations, and extreme events, such as heavy precipitation and winter cold days, are better represented. Although the ensemble size is still relatively small at only 12 members, the simulations provide meteorologically-consistent scenarios on all timescales from hours to decades and from the local to the national scale, which can be used to drive impacts models. The improved synoptic variability in HadGEM3 and the better representation of extremes in the regional simulations should enable greater stress testing of the UK's resilience across a range of hazards and their impacts.

Finally, UKCP18 included for the first time, internationally, an ensemble of local simulations at an unprecedented resolution of 2.2km, equivalent to the resolution currently being used for operational ensemble weather forecasting for the UK (see UKCP Convection-Permitting Model Projections: Science Report, 2019). Again, the ensemble is based on HadGEM3 and uses the same global model driving fields as the regional 12km ensemble. The aim of this ensemble is to provide information on local extremes, such as sub-daily rainfall and wind gusts associated with, for

example, sting jets. There are numerous examples in operational weather forecasting highlighting the value of this class of simulations, especially for severe weather warnings.

**Figure A1.1** Normalised root-mean-squared errors (RMSE) in global, annual spatial fields of a variety of climate variables from the 28 Strand 2 simulations, averaged over 1981-2000 versus observational estimates from ECMWF reanalysis and satellite data. The climate variables span metrics that cover radiation, temperature, precipitation, winds, surface pressure and geopotential height. The 13 CMIP 5 simulations used in UKCP18 are to the right and the HadGEM3 simulations to the left. The scores are normalised by the RMSE for the best-performing simulation for a given variable, which therefore possesses a value of 1.0. The plot is presented as a “heatmap”, in which simulations with the highest normalised errors, and therefore the worst performance, are shown as the darkest shades of purple. Some entries are missing for EC-EARTH, due to unavailability of data. Reproduced from Murphy et al. (2018)

The UKCP18 2.2km ensemble was published in September 2019 and so has only been used to a limited extent in CCRA3. In future, the value of the convection-permitting model (CPM) ensemble can be expected to be increasingly realised for providing detailed spatial and temporal extreme scenarios to stress test the UK’s preparedness and resilience policies at the local level. This was demonstrated for earlier applications of the CPM for the National Flood Resilience Review analysis of the fit-for-purpose of the Extreme Flood Outlines (National Flood Resilience Review 2016).

In summary, climate science and important aspects of the skill of the climate models have advanced significantly since CCRA2. These advances are embodied primarily in the new family of global and regional models, based on HadGEM3, which is an important part of UKCP18. However, the climate

sensitivity of HadGEM3 (Andrews *et al.*, 2019) is significantly higher than earlier Hadley Centre global models, such as HadCM3 used in UKCP09 and HadGEM1 used in IPCC AR5. It is also higher than the cohort of CMIP5 models, which was used in CCRA2, but in line with a number of recently developed models being used in CMIP6 for the IPCC AR6. As Andrews *et al.* (2019) note, none of the model's forcing and feedback processes are found to be atypical of other models, although the cloud feedback is at the high end.

CCRA3 is framed in terms of trajectories of global warming rather than emissions scenarios. Research commissioned on some of the risks therefore used selected components of the UKCP18 projections representing global warming of approximately 2°C and 4°C by the end of the century. The assessment of other risks draws on literature using other models, projections and scenarios that give approximately 2°C and 4°C global warming by 2100.

## A1.2 Methods for climate projections

This section summarises the methods used for the latest projections of future changes in the UK's climate during the 21<sup>st</sup> Century. It draws on the detailed reports produced for the new UK climate projections UKCP18 (Gohar *et al.*, 2018; Kendon *et al.*, 2019; Murphy *et al.*, 2018; Palmer *et al.*, 2018) the emerging literature from the latest global climate models in preparation for IPCC AR6, and analysis by Hanlon *et al.* (2021a). Comparisons with earlier climate projections are also made, since much of the impacts and risks literature assessed in CCRA3 uses these.

UKCP18 consists of several components which are useful for different aspects of climate change risk assessment.

1. Probabilistic projections of climate over UK land which draw together information from perturbed-parameter ensembles with the HadCM3 model and the multi-model ensemble in CMIP5. These give an estimate of the likelihood of particular changes, e.g., long-term average temperature or precipitation change across the UK, from the present day to 2100. The changes at each gridpoint are independent from each other – they are not intended to provide a coherent picture of change across the country, just likelihood of change in individual locations.
2. A set of global projections at 60km resolution out to 2100 which are spatially coherent, i.e., each individual projection represents climates that could occur simultaneously across the world. Overall, the projected changes across the whole set cover a similar range to those in the probabilistic projections described above, but individual projections are not assigned likelihoods. Within this set, the HadGEM3 model provides a subset of projections. Due to the behaviour of HadGEM3, this subset of projections tends to be at the warmer end of the range of probabilistic projections. The other subset uses projections from other climate models developed by other modelling centres, as part of the 5<sup>th</sup> Coupled Model Intercomparison Project (CMIP5). The range of outcomes from the CMIP5 subset covers a similar range to the probabilistic projections.
3. A set of regional projections of climate over land out to 2100 at 12km resolution, covering the UK. These are driven at their boundaries by output from the global simulations with the HadGEM3 subset of the global projections and provide a more detailed simulation of the

climate at the UK scale. Again, because they use HadGEM3 boundary conditions, the projections are at the warmer end of the range of the probabilistic projections.

4. A further set of local projections of climate over land at 2.2km resolution, for selected time periods during the 21<sup>st</sup> Century. These higher-resolution models are designed to provide a more realistic simulation of key meteorological processes, particularly convection, and are particularly for simulating extreme events such as heavy rainfall or high daily maximum temperatures.
5. A set of projections of long-term sea level rise, storm surges and changes in wave height for UK coastlines
6. A set of projections derived from the above, representing long-term climate states at 2°C and 4°C global warming and a low-emissions scenario

The regional simulations are driven by HadGEM3 boundary conditions, so the output is influenced not only by HadGEM3's higher climate sensitivity but also its representation of important weather regimes. These are summarised in Section A1.3 where they are placed in context with the probabilistic projections and global model simulations. Due to the computational cost of the high-resolution regional simulations with HadGEM3, regional climate change scenarios were only produced with one emissions scenario to allow for the largest possible ensemble size to be utilized in order to cover a wide range of regional climate outcomes. The highest emissions scenario, RCP8.5, was chosen so that the widest range of future levels of global warming could be explored, including the most extreme climate changes considered as low-probability, high-impact scenarios.

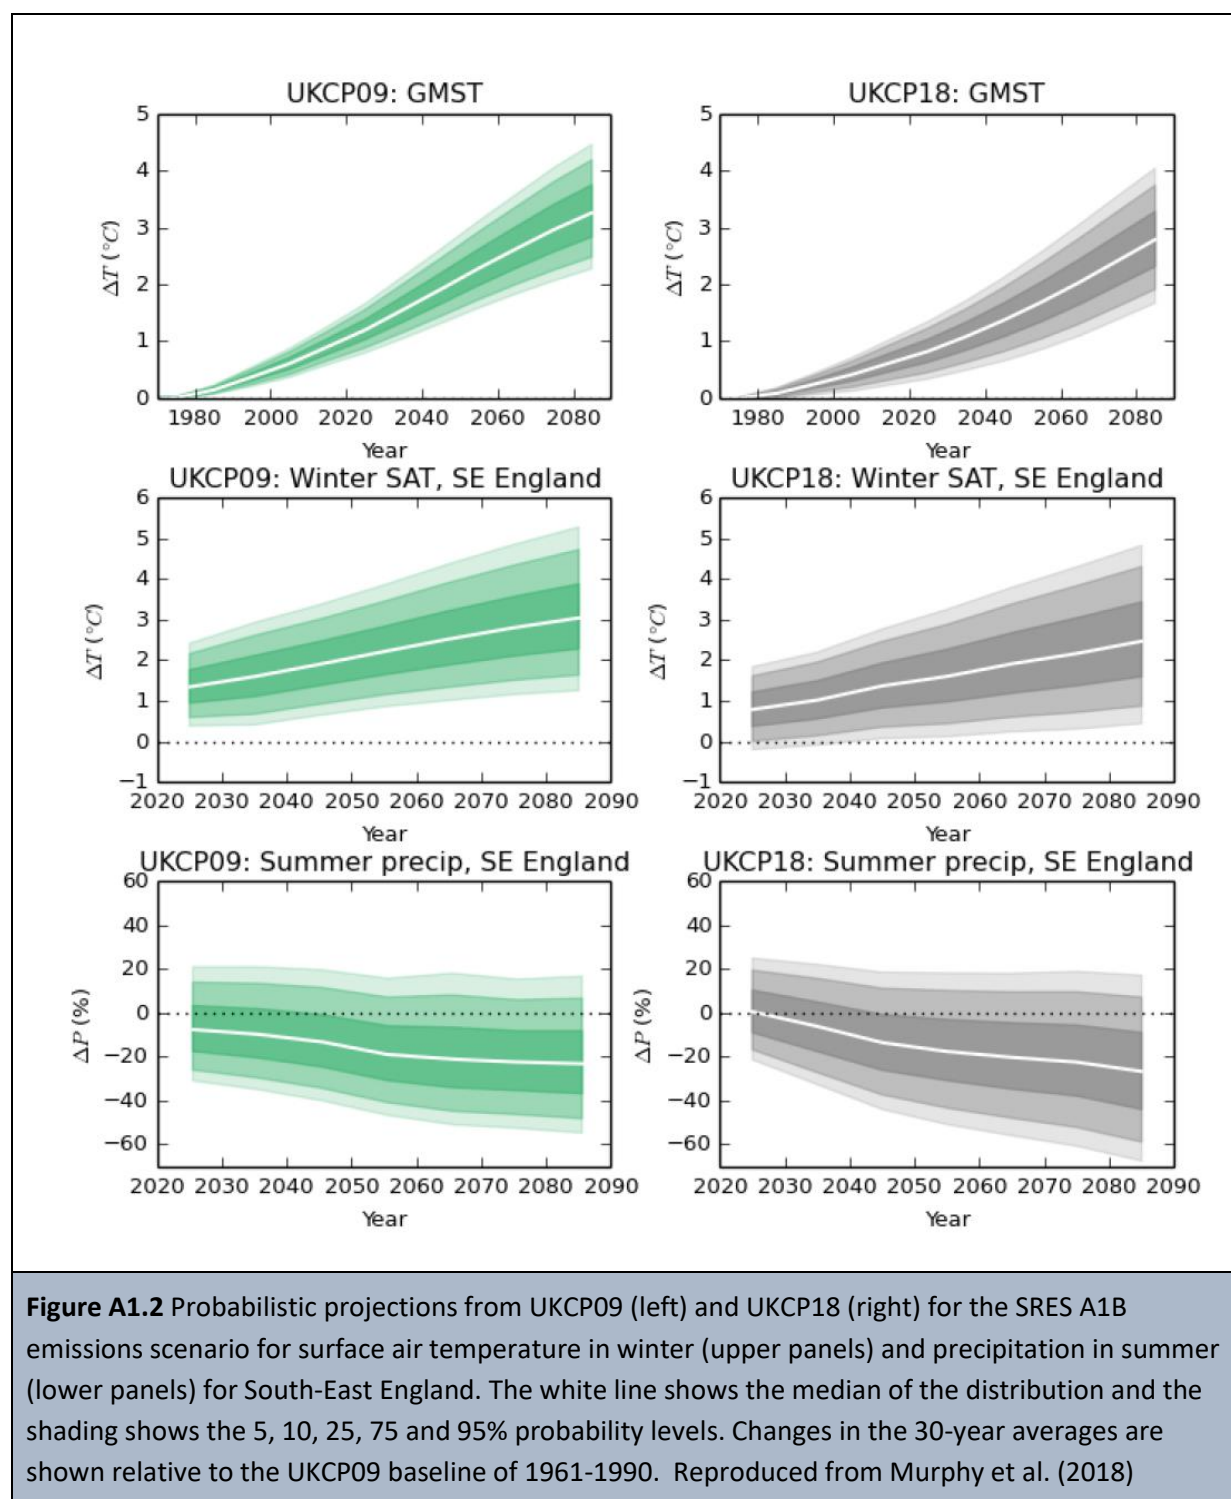

Nevertheless, for many climate impact drivers, the projected regional changes at particular levels of global warming can be considered to be representative of the same level of global warming reached at a later date with a lower emissions scenario and/or as a result of a lower climate sensitivity.

The regional projections basically reflect the driving boundary conditions of HadGEM3. In winter the results mostly lie within the range of the probabilistic projections but indicate slightly wetter and warmer winters than in previous assessments, consistent with the increase in cyclonic weather types in HadGEM3 and its higher climate sensitivity. In summer, however, the regional projections are substantially different and are towards the hotter, drier end of the range of the probabilistic projections. Both Scotland and England are projected to be 1-2°C warmer than the earlier CMIP5 models, associated in part with HadGEM3's higher climate sensitivity. For England, there is a very strong signal for much reduced rainfall, which is in line with the link between the phase of the SNAO and summer rainfall noted earlier and therefore not due entirely to the higher climate sensitivity.

### A1.3 Comparison of UKCP18 with UKCP09 and other climate projections

Figure A1.2 shows that the trajectories of the 30-year average UK climate are very similar in UKCP18 and UKCP09 when considering a consistent emissions scenario, with the differences at any particular percentile level being much smaller than the 5<sup>th</sup> to 95<sup>th</sup> percentile spread. This provides reassurance that the evidence for the ongoing trend towards increased likelihood warmer, wetter winters and hotter, drier summers is unchanged. This consistency with UKCP09 on the overall trajectory of long-term average climate change is important because much of the climate risk literature available for CCRA3 uses UKCP09.

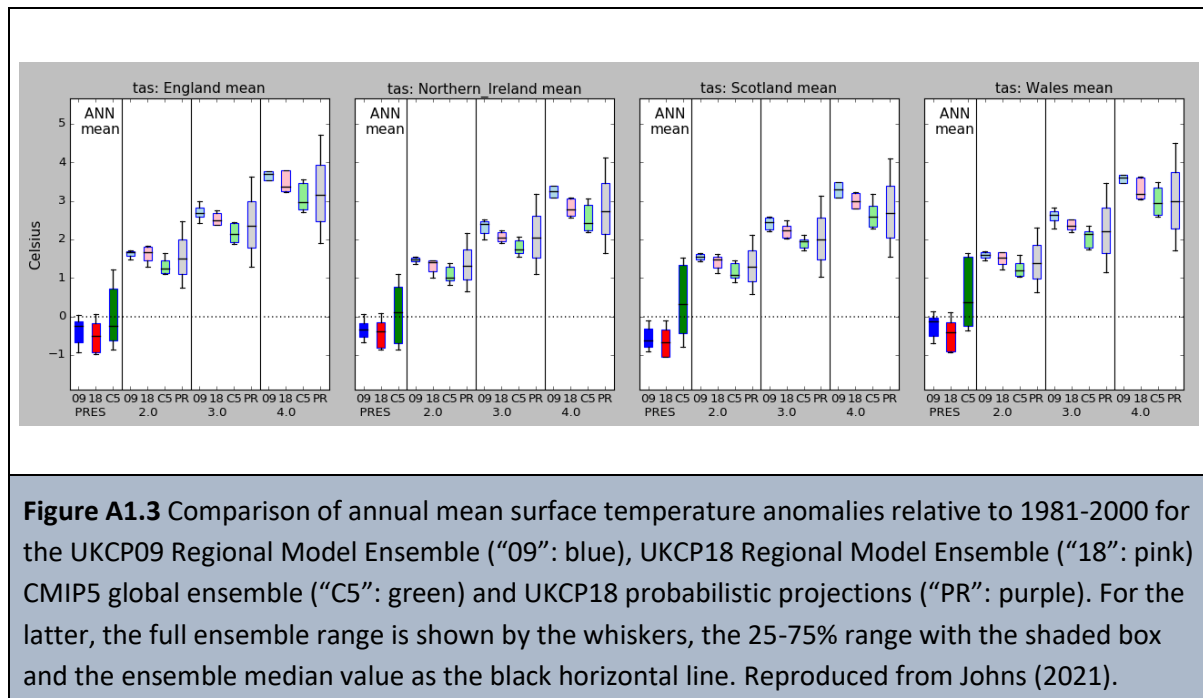

CCRA3 commissioned a detailed comparison of these climate metrics based on processed daily data from the regional climate model (RCM) perturbed parameter ensemble components of UKCP18 and UKCP09 (Johns, 2021). In order to place the UKCP results in a broader modelling uncertainty context, results have also been compared to an ensemble of 13 selected CMIP5 global projections, analysed in a similar way using available daily data. The analysis considered future changes in the metrics of interest through the 21<sup>st</sup> Century relative to a present-day baseline of 1981-2000, with a focus on

changes at specified global warming levels ranging through 1.5, 2, 3 and 4 °C relative to preindustrial.

Reframing the results in terms of 20-year time slices centred on 2, 3 and 4 °C of global mean warming shows that the UKCP18 regional model ensemble actually exhibits relatively lower warming than the UKCP09 regional model ensemble over all UK nations for any given level of global warming (Figure A1.3). However, the UKCP18 results are higher than those based on global CMIP5 model results. Figure A1.3 also shows the bias in the various ensembles for the present day so that the projected climate change can be put in context.

#### A1.4 Emissions scenarios and concentration pathways in the RCPs

Studies of future climate change impacts and risks using climate model projections use different approaches to the representation of future emissions scenarios. Some, such as UKCP09 and UKCP18, use Earth System Models to calculate a more complete climate system response to a given emissions scenario, including modelling the carbon cycle interactively with the atmosphere and oceans. Others, such as CMIP5, do not model the carbon cycle and instead assign a specific scenario of CO<sub>2</sub> concentrations based on other models. In order to compare or integrate results from these projections correctly, it is important to appreciate the differences between these approaches. Unfortunately, for the RCP scenarios, the same terminology is used in the literature for both emissions scenarios and concentration pathways, and this can often lead to a lack of clarity and poor understanding of the context of research studies of climate change risks.

The RCPs (Representative *Concentration* Pathways) are defined in terms of levels of radiative forcing at the end of the 21<sup>st</sup> Century, which is due to particular level of atmospheric concentrations of greenhouse gases and aerosols. Each RCP has a standard pathway of atmospheric CO<sub>2</sub> concentrations, and it is these concentration pathways that are used as input most climate projections of the CMIP5 generation, including those used in the IPCC 5<sup>th</sup> Assessment Report (IPCC,

2013). For example, in RCP8.5, the radiative forcing in 2100 is  $8.5 \text{ Wm}^{-2}$ , and the  $\text{CO}_2$  concentration at that time in the standard RCP8.5 concentration pathway is 936 parts per million (ppm) (Booth et al., 2017).

However, the same term (RCP) is also applied to specific *emissions* scenarios that are conventionally associated with these concentration pathways. For example, in the standard RCP8.5 emissions scenario, the cumulative  $\text{CO}_2$  emissions from 2020 to 2100 are 6629 Gigatonnes of  $\text{CO}_2$  ( $\text{GtCO}_2$ )<sup>13</sup>. These emissions scenarios are used in other climate models using a different approach to the main CMIP5 models, taking the emissions as input and then calculating the  $\text{CO}_2$  concentrations within the model. The UKCP18 projections uses this approach.

A critical point about the differences between these approaches is that there is uncertainty in the strength of carbon cycle feedbacks in the climate system, with the result that:

- a) Any given emissions scenario can give rise to a wide range of future concentration pathways
- b) Any specific future concentration pathway can arise from a wide range of emissions scenarios

In UKCP18, the probabilistic projections include an exploration of uncertainties in carbon cycle feedbacks, and hence effectively represent a range of  $\text{CO}_2$  concentrations compatible with each RCP emissions scenario, not just the standard RCP concentration pathways used in CMIP5. This should be borne in mind when comparing the CMIP5 projections with UKCP18 projections using apparently the same scenario - even though both are labelled “RCP”, the scenarios have been applied differently. The standard RCP8.5 concentration pathway used in the CMIP5 projections is in the lower part of the range of concentrations compatible with the RCP8.5 emissions scenario using a coupled climate-carbon cycle model. (Booth et al., 2017; Murphy et al., 2018; Figure A1.4)

<sup>13</sup> <https://tntcat.iiasa.ac.at/RcpDb/dsd?Action=htmlpage&page=compare>

**Figure A1.4** Projected changes in atmospheric CO<sub>2</sub> concentration associated with the RCP8.5 emissions scenario. Red (“STD”): the standard CO<sub>2</sub> concentration pathway for RCP8.5 as used in CMIP5. Orange (“GC3.05-PPE”): several CO<sub>2</sub> pathways simulated with Earth System Models driven by the RCP8.5 emissions scenario, including feedbacks between climate change and the carbon cycle, constrained against observations of the historical CO<sub>2</sub> rise following Booth *et al.* (2017). Grey plume (“Land strand 1”): probability distribution of CO<sub>2</sub> concentrations used in the UKCP18 probabilistic projections driven by the RCP8.5 emissions scenario, with 5<sup>th</sup> and 95<sup>th</sup> percentiles in black. Reproduced from Murphy *et al.* (2018).

This difference in methodology is an important factor in causing the UKCP18 RCP8.5 emissions-driven probabilistic projections to simulate a much wider range of levels of global warming by 2100 than the CMIP5 RCP8.5 concentrations-driven projections, with the upper end of the UKCP18 range being considerably higher than that of the CMIP5 range (see Figure A1.3). It is also one reason for very rapid projected warming in the UKCP18 60km resolution global projections with the HadGEM3 perturbed-parameter ensemble (the other reason being the high equilibrium climate sensitivity / transient climate response).

An important implication of this is that climate projections driven by RCP concentration pathways could arise from different emissions scenarios from the ones conventionally associated with the RCP pathways used. For example, the RCP8.5 concentration of 936 ppm can be reached by a much lower emissions scenario than the standard RCP8.5 emissions scenario. In the SRES A1B emissions scenario (Nakićenović, N. *et al.*, 2000), cumulative emissions are approximately two-thirds of those in the RCP8.5 emissions scenario, but in a perturbed-parameter ensemble of a coupled climate-carbon cycle model constrained against observed changes in CO<sub>2</sub> concentrations, these emissions lead to a wide range of CO<sub>2</sub> concentrations by 2100 which include the 936 ppm of the standard RCP8.5 pathway (Figure A1.5).

In conclusion: due to substantial uncertainties in translating emissions to concentrations, there is no single one-to-one relationship between an emissions scenario and a concentration pathway. This can lead to confusion over the interpretation of the scenario and the level of climate change impact that it represents. Nevertheless, the use of the same term “RCP” for both emissions scenarios and concentration pathway is common, so for clarity it is helpful to specify whether particular projections used RCP emissions scenarios or RCP concentration pathways.

## Annex 2: Threshold Exceedance Metrics

A goal of CCRA3 is to look beyond long-term climatic trends to include volatility of the weather and climate at the regional and local scales. It is the case that some of the more costly, disruptive and dangerous impacts of climate change will be associated with increased frequency and/or intensity of extreme weather and climate events. Furthermore, some of these impacts only come into play, or become very serious, when certain meteorological thresholds are exceeded (Table A2.1).

There is also now the possibility of applying threshold exceedance metrics to the UKCP18 2.2km time-slice scenarios, especially those related to extreme daily and sub-daily rainfall linked to embedded frontal convection and summer thunderstorms, to investigate how the current risk evolves under climate change. Similar to the UNSEEN methodology we can use the 12-member ensemble for 1981-2000 to provide 240 ‘years’ of synthetic observations of the current risk of exceeding certain impact thresholds. This will add to our understanding of the baseline risk from extreme events, which is currently very limited due to the shortness of the observational record. The same analysis can then be applied to the 240 ‘years’ for 2021-2040, which will provide a first assessment of how these metrics may change under near-term climate change. This may provide a valuable tool for CCRA4.

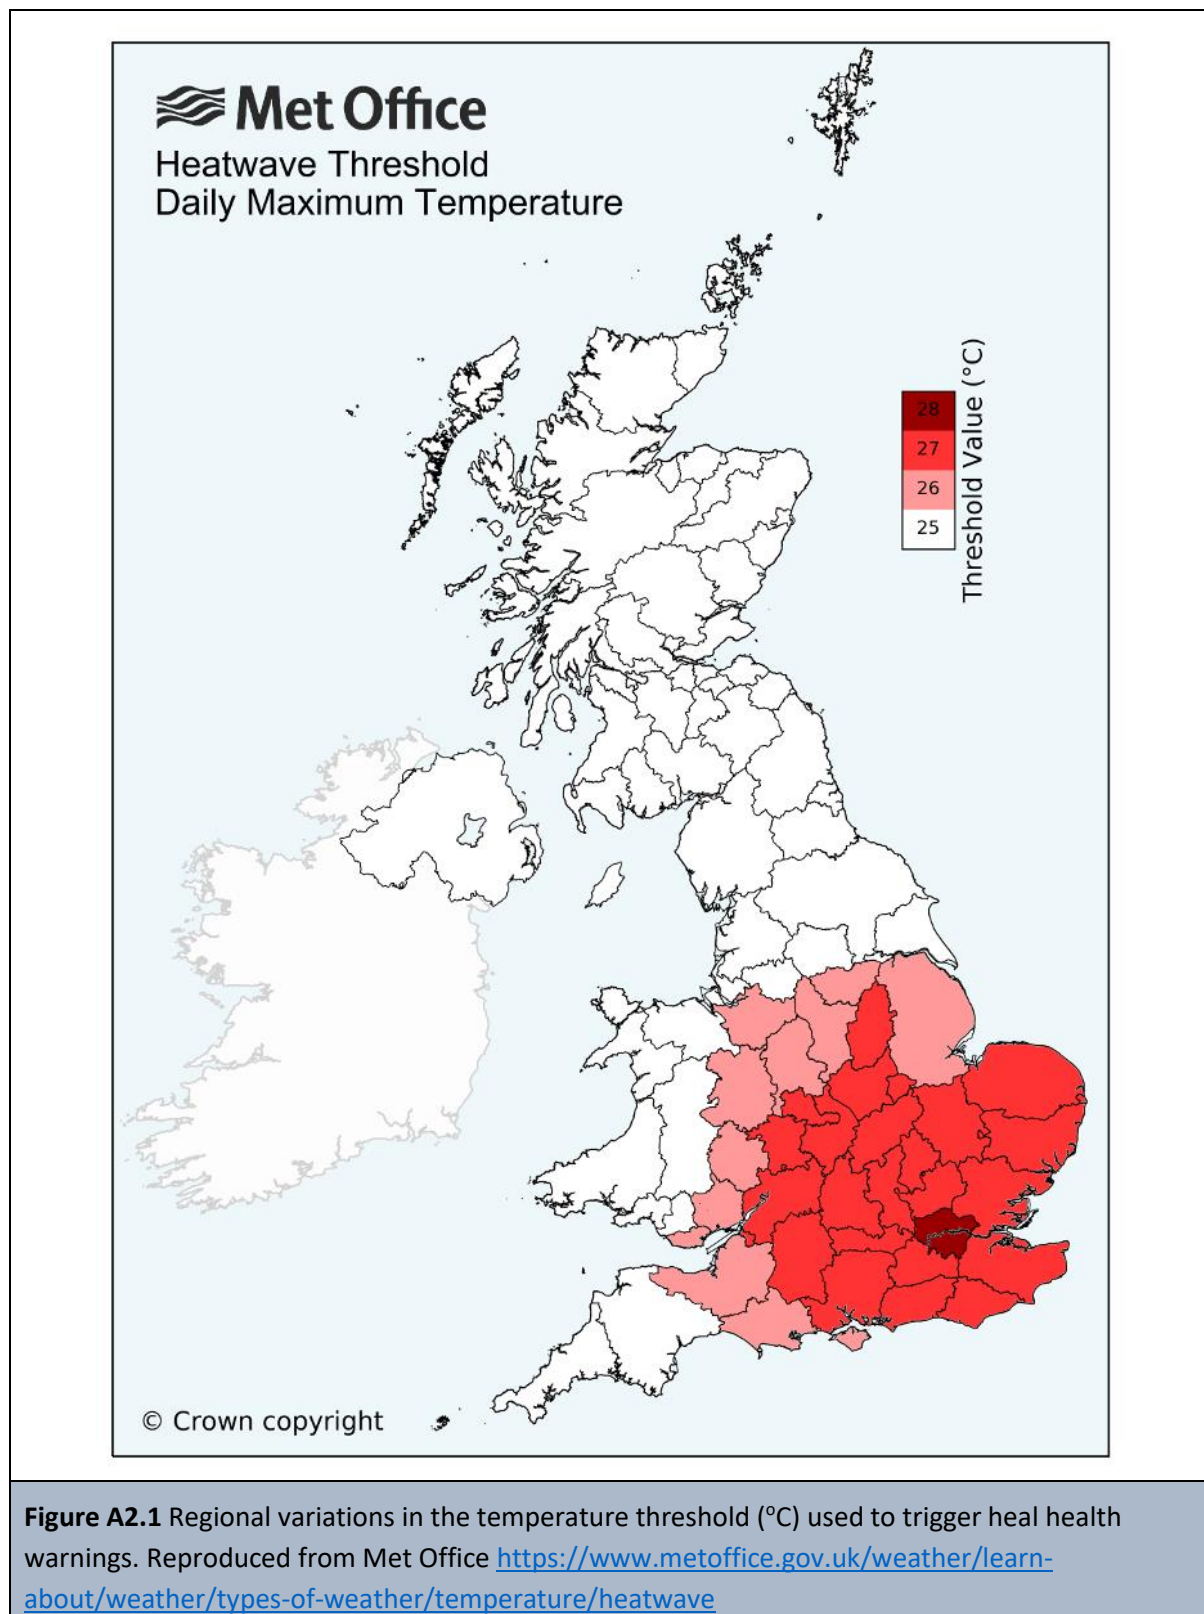

Table A2.1: Impact indices		
Index	Threshold	Impact relevance
<b>Frost Days</b>	Daily minimum temperature below 0°C	Cold-weather disruption due to higher than normal chance of ice and snow.
<b>Icing Days</b>	Daily maximum temperature below 0°C	More extreme than frost days, so more severe cold-weather impacts.
<b>Tropical Nights</b>	Daily minimum temperature above 20°C	Health impact due to high night-time temperatures with potential for heat stress. Vulnerable people at increased risk of hospital admission or death.
<b>Summer Days</b>	Daily maximum temperature above 25°C	High daytime temperatures with health impacts for vulnerable people at risk of hospital admission or death. Transport disruption – e.g., track buckling on railways.
<b>Rainfall meeting National Severe Weather Warning Service (NSWWS) criteria</b>	Thresholds, which vary regionally, and is applied as proxy for Low/Medium/High impacts	Informative for estimating periods of increased risk of river flooding (fluvial flooding only). Note these are not appropriate for assessing pluvial flooding (surface water flooding).
<b>Drought Severity Index</b>	This index is not threshold based. Instead, it is calculated with 3-, 6-, 12- and 36-month rainfall deficits	3-month – meteorological/agricultural drought, a short intense dry period leading to low soil moisture levels impacting crop growth.  6-month – longer and higher impact agricultural drought.

		12-month – hydrological drought leading to low water supply nationwide.  36-month – longer term hydrological drought leading to low water supply nationwide.
<b>Wind gusts meeting National Severe Weather Warning Service (NSWWS) criteria</b>	Thresholds, which vary regionally, and is applied as proxy for Low/Medium/High impacts	Transport disruption, infrastructure or building damage, bridge collapse and trees falling
<b>Growing Degree Days</b>	Daily Mean temperature above 5.5°C	Energy available for plant growth over a year. Not a measure of season length.
<b>Heating Degree Days</b>	Daily Mean temperature below 15.5°C	Indicator of meteorological contribution to energy demand for heating.
<b>Cooling Degree Days</b>	Daily Mean temperature above 22°C	Indicator of meteorological contribution to energy demand for cooling.

Exceedance metrics are currently used in Met Office National Severe Weather Warning Service (NSWWS), which issues warnings when severe weather has the potential to impact the UK. These warnings are based on a combination of the likelihood of the weather event occurring at any location, and the severity of the impacts if that event happens, where the severity is based on historical links between severe weather and its impacts in different parts of the country. This geographic variation in thresholds reflects the variations in both the exposure of populations and infrastructure, as well as the vulnerability of natural and human systems to these extreme conditions.

Alongside the NSWWS, the Met Office also produces a ‘heat health watch’ service for health professionals, contingency planners and emergency responders for planning purposes. This metric is based on exceedance of daily maximum temperature thresholds for least 3 consecutive days. Again, the thresholds vary geographically, as shown in Figure A2.1 and take account of the urban heat island effects in London.

The World Climate Research Programme (WCRP) and World Meteorological Organization (WMO) Expert Team on Climate Change Detection and Indices (ETCCDI) have defined a set of 27 core indices

(the 'ETCCDI' indices<sup>14</sup>) which can be derived from land surface observations of daily temperature and precipitation. A selection has been used in the Met Office's State of the UK Climate reports (Kendon *et al.*, 2018 and McCarthy, 2018) to study observed changes in the UK climate. These can be used in CCRA3 to inform possible changes in the frequency of threshold exceedance, which may have an impact on natural, human and business systems. These differ from the NSWWS metrics which focus on extreme events.

2.2km CPM timeslice scenarios for 1981-2000 and 2021-2040 to provide new estimates of the baseline and near-term climate change risks associated with extreme events at the local scale. For example, based on 3 hourly rainfall, exceedances of 30mm/hour (and potentially 100mm/hour) at any location are currently being studied with respect to surface flooding.

Table A2.2, based on the NSWWS, shows the threshold exceedances that are likely to have a high impact today, and provide a suitable baseline for considering high impact exceedances in the future, where adaptation may be required. The metric refers to any location in the geographical region. Daily rainfall is used to inform forecasters on the possibility of river flooding and these metrics would be applicable to the UKCP18 12km simulations.

<b>Table A2.2 Met Office National Severe Weather Warning Service (NSWWS) thresholds</b>		
<b>NSWWS Index based on 12km UKCP18</b>	<b>Geographical Region</b>	<b>Exceedance Metric</b>
<b>Max 10m Wind gust (winter)</b>	South East England	≥ 70 mph
<b>Max 10m Wind gust (winter)</b>	Highlands and Islands	≥ 90 mph
<b>Max 10m Wind gust (winter)</b>	Rest of the country	≥ 80 mph
<b>Max 10m Wind gust (summer)</b>	South East England	≥ 65 mph
<b>Max 10m Wind gust (summer)</b>	Highlands and Islands	≥ 80 mph
<b>Max 10m Wind gust (summer)</b>	Rest of the country	≥ 70mph
<b>24-hour precipitation</b>	England and Wales	≥ 80 mm
<b>24-hour precipitation</b>	Northern Ireland	≥ 80 mm
<b>24-hour precipitation</b>	NW Scotland	≥ 80 mm
<b>24-hour precipitation</b>	SW Scotland	≥ 65 mm
<b>24-hour precipitation</b>	South and East Scotland	≥ 55 mm
<b>24-hour precipitation</b>	NE Scotland	≥ 75 mm
<b>Maximum Temperature</b>	Geographically varying (see Figure)	≥ 25-28°C for 3 consecutive days

<sup>14</sup> [http://etccdi.pacificclimate.org/list\\_27\\_indices.shtml](http://etccdi.pacificclimate.org/list_27_indices.shtml)

The ETCCDI indices (Table A2.3) identify aspects of our changing climate that influence the functioning of natural ecosystems and aspects of demands on infrastructure. They complement the NSWWS extreme indices.

<b>Table A2.3</b> World Meteorological Organization Expert Team on Climate Change Detection and Indices (ETCCDI) Indices			
<b>ETCCDI Index based on 12km UKCP18</b>	Variable	Threshold	Count
<b>Frost Days</b>	Daily Minimum Temperature	< 0 °C	Days below this threshold
<b>Icing Days</b>	Daily Maximum Temperature	< 0 °C	Days below this threshold
<b>Tropical Nights</b>	Daily Minimum Temperature	> 20 °C	Days above this threshold
<b>Summer Days</b>	Daily Maximum Temperature	> 25 °C	Days above this threshold
<b>Growing Degree Days</b>	Daily Mean Temperature	> 5.5 °C	Degrees above this threshold per day
<b>Heating Degree Days</b>	Daily Mean Temperature	< 15.5 °C	Degrees below this threshold per day
<b>Cooling Degree Days</b>	Daily Mean Temperature	> 22 °C	Degrees above this threshold per day

## Executive Summary

This chapter sets out the methodology for the Third UK CCRA Technical Report (CCRA3). The Technical Report informs the CCRA3 Advice Report, which is written by the Climate Change Committee, and these two documents together are the core components of the CCRA3 Independent Assessment.

In line with the Climate Change Act 2008, the objective of the CCRA is to consider current and future climate-related risks and opportunities to the UK, and the extent to which current or planned policies address these. To help guide this, the CCRA3 Technical Report uses the following key question:

**Based on the latest understanding of current and future climate risks and opportunities, as well as current and planned adaptation, what should the priorities be for the next National Adaptation Programme and adaptation programmes of the devolved administrations?**

The aim of the CCRA3 Technical Report is to inform planned adaptation from government, agencies, regulators, etc., including both direct intervention and/or to create the enabling environment to help others adapt (e.g. the private sector, households). It seeks to inform the adaptation programmes of the individual countries of the UK (England, Northern Ireland, Scotland and Wales) and this determines the aggregation and reporting level. The priority for the Technical Report is, therefore, to identify where action is needed in the next five years to manage climate change risks or opportunities that may arise over the short, medium and longer-term.

As with CCRA2, the CCRA3 Technical Report uses a synthesis approach. It draws on a large body of peer-reviewed scientific literature and other quality-assured literature on climate change, risks and adaptation, complemented by new research studies in key areas. This requires a harmonised and consistent approach to consider and collate evidence from different sectors and source material: this chapter sets out this approach.

The method developed in CCRA3 builds on requirements set out by Defra and the devolved administrations and an initial method statement developed by the Climate Change Committee (CCC). This was developed further by the CCRA3 Evidence method team authors. It uses the same broad approach as CCRA2, but with some evolution to reflect lessons from CCRA2 and the second round of national adaptation programmes, as well as developments in the climate risk assessment and adaptation literature over the past five years.

The CCRA3 Evidence method is based on the prioritisation of risks and opportunities using an analysis of urgency. This seeks to identify where action is most urgently needed over the next five-year period using three questions:

1. What is the current and future level of risk/opportunity?
2. Is the risk/opportunity being managed, based on government commitments and other adaptation actions?
3. Are there benefits to further action in the next five years, over and above that already planned?

For the CCRA3 Technical Report, we have aligned the methodology to the three questions above, thus there are three steps:

- Step 1) Analysis of the magnitude of current and future risks and opportunities;
- Step 2) Analysis of the benefits of current and planned adaptation;
- Step 3) Analysis of overall urgency and the benefits of additional adaptation.

For the third of these steps, the CCRA3 uses a complementary framework to help to identify adaptation priorities, as well as what type of additional action could be useful. This approach builds on a well-established literature that was also included in CCRA2. It aims to identify three types of early adaptation priorities that can help address risks and opportunities within the next five-years:

- To address any current adaptation gap by implementing ‘no-regret’ or ‘low-regret’ actions that reduce risks associated with current climate variability, as well as building future climate resilience.
- To intervene early to ensure that adaptation is considered in near-term decisions that have long lifetimes and therefore reduce the risk of ‘lock-in’, such as for major infrastructure or land-use developments.
- To fast-track early adaptive management activities, especially for decisions that have long lead times or involve major future change. This can enhance learning and allows the use of evidence in forthcoming future decisions.

These three priorities are not mutually exclusive, and a combination of all three is often needed as part of a portfolio at the national level.

At the end of this analysis, based on the evidence, each risk or opportunity is ranked into one of four urgency scores: i) “more action needed”; ii) “further investigation”; iii) “sustain current action”; or iv) “watching brief”.

A number of updated or new elements have been included in the CCRA3 Evidence method. These include the following:

- A new set of UK Climate Projections were published in 2018, 2019 and 2020, called UKCP18. However, it takes several years for the risk and impact literature to use these projections in published studies, and much of CCRA3 is therefore based on literature that uses the previous set of projections, UKCP09. CCRA3 has therefore assessed what has changed from UKCP09 to UKCP18, and has produced guidance on how to interpret exiting literature using the new UKCP18 results (see also Chapter 1 (Slingo, 2021) and section 2.2 of this chapter).
- There is a greater focus in CCRA3 on looking at changes in climate variability (volatility) and new methods for considering unprecedented events that could occur in the current climate. CCRA3 has also considered the potential risks of low-likelihood, high-impact outcomes, which includes High++ scenarios and major discontinuities (globally or regionally) (see Chapter 1 (Slingo, 2021) and section 2.2 of this chapter).
- CCRA3 has considered interacting risks and interdependencies for each risk / opportunity, rather than as part of a cross-cutting chapter (as in CCRA2). There is also consideration of the inequalities associated with risks and opportunities.

- There is a greater focus on considering the type of further adaptation that could be possible, and on the benefits of additional action. A lesson from CCRA2 is that evidence to inform adaptation needs to be collected and assessed earlier in the analysis. CCRA3 therefore has a greater emphasis on the risks of lock-in and thresholds, as part of step 1 (see section 2.3). There is also more emphasis on adaptive management, encouraging the consideration of evolving risks over time, including a more explicit linkage to CCRA4 (see section 2.3).
- There has been more consideration of the economic costs (or benefits) of individual risks and opportunities (reported in a separate monetary valuation analysis) and an analysis of the indicative costs and benefits of further adaptation. n the indicative costs and benefits of further adaptation.
- Finally, during the period that the analysis for the CCRA3 Technical Report was undertaken, the UK, Scottish and Welsh Governments adopted Net Zero greenhouse gas emissions targets into law. The measures needed to achieve Net Zero may be sensitive to climate hazards, particularly in the buildings and land use sectors. To investigate this, CCRA3 has considered possible relevant climate risks or opportunities for different types of mitigation measures, and also considered synergies and trade-offs between mitigation and adaptation actions (see section 2.5).

## 2.1. Introduction

### 2.1.1 Context and Objectives

**The UK's Climate Change Risk Assessment (CCRA) aims to analyse the risks and opportunities from climate change to the UK, with the goal of informing the priorities for the UK Government's National Adaptation Programme (NAP) as well as the adaptation programmes of the devolved administrations (DAs).**

The UK CCRA is undertaken on a five-year rolling cycle and is now on its third cycle. This chapter sets out the approach used for the **Third CCRA Technical Report**, to be published in 2021. The objective of the Technical Report is to review and analyse the evidence on priority risks and opportunities for England, Northern Ireland, Scotland and Wales and by doing so, to help provide information of relevance for the next round of Government-led adaptation programmes. The Technical Report informs the CCRA3 Advice Report, which is written by the Climate Change Committee, and these two documents are core components of the CCRA3 Independent Assessment. This Assessment informs the CCRA3 Government Report (due for publication in 2022) and the third NAP and the third adaptation programmes of the devolved administrations (DAs), due to be published from 2023. The information in the CCRA3 Technical Report is, however, also likely to be of interest to a wider audience.

For practical purposes, the CCRA3 Technical Report sets out to address the following key 'exam' question:

**Based on the latest understanding of current and future climate risks and opportunities, as well as current and planned adaptation, what should the priorities be for the next National Adaptation Programme and adaptation programmes of the devolved administrations?**

These adaptation programmes may include direct public sector action (by government, agencies, regulators, etc.), but also interventions that create the enabling environment for others to adapt, i.e. for utilities, the private sector and households. To provide this information, the CCRA focuses on the urgency of risks and opportunities. Urgency is defined as a measure of the level of action that is needed in the next five years to reduce a risk or realise an opportunity from climate change, noting that these near-term actions may address risks or opportunities in the short, medium or long-term. To ensure that the information provided is relevant for the respective adaptation programmes, the assessment is undertaken for each individual country (England, Northern Ireland, Scotland and Wales), rather than for the UK.

In addition, unless it conflicts with the primary aim, the CCRA3 Technical Report also has a set of secondary goals, which are:

- To inform investment and policy decisions where there are material climate risks for other organisations or actors, e.g. for the private sector (including small to medium sized businesses) or households. This has links to recent initiatives on financial climate risk disclosure and reporting (TCFD, 2017; NGFS, 2019) and also the UK Green Finance Strategy (HMG, 2019);

- To show progress from CCRA1 (HRW, 2012a) and from CCRA2 (CCC, 2016) on how our understanding of the level of current and future risk, as well as the management of these risks by Government, has changed; and
- To act as a stepping-stone to CCRA4 in terms of the approach, framing and information needs.

The CCRA3 Technical Report draws on a well-informed practitioner community and a rich legacy of previous climate risk assessments. It updates the previous CCRA2 by drawing on evidence produced in the intervening five years. It also includes an update to the methodology used for the assessment, taking advantage of the fact that the five-year UK CCRA cycle allows for a process of evaluation and learning. This has led to an evolution in the method used for successive assessments, i.e. from CCRA1 to CCRA2, and CCRA2 to CCRA3.

In the first and second CCRAs, the assessment of risks was presented in an Evidence Report. In CCRA3, the Independent Assessment consists of a substantial set of reports and other documents including this Technical Report and the CCC's Advice Report. As with the CCRA2 Evidence Report, the CCRA3 Technical Report is based on a synthesis exercise, rather than a new national quantified assessment. It draws on the large body of peer-reviewed scientific literature and grey literature on climate change, risks and adaptation in the UK, complemented with new CCC commissioned research in key areas. It uses this evidence alongside expert judgement in assessing risks and opportunities, building on expertise in the international context (e.g. Mach et al., 2017) as well as previous CCRAs. However, this synthesis approach means that the CCRA3 draws on literature that has used different methods, scenarios and assumptions.

**The key aim of the CCRA3 method chapter is to set out a harmonised approach to: gather evidence from the wide range of source material; to analyse this evidence consistently; and to present it in ways that make it easier for the UK Government and the devolved administrations to respond. This chapter sets out this approach.**

The method developed for the CCRA3 Technical Report responded to requirements set out (in a document) by Defra and the devolved administrations (produced in 2018).

It was further developed by the CCRA3 Evidence method team authors, working in partnership with the Climate Change Committee, who led the overall programme to produce the Independent Assessment, and with inputs and comments from the peer review process. The method development drew on lessons from the second CCRA Evidence Report (CCRA2), published in 2016 (CCC, 2016), the latest climate science including the new UK Climate Projections (UKCP18), and the updated approaches to climate change risk and adaptation assessment presented in the IPCC Fifth Assessment Report (IPCC, 2014a), the Special Reports on Global Warming of 1.5°C (IPCC, 2018a) and on the Ocean and Cryosphere in a Changing Climate (IPCC, 2019). A summary of the methodological development of the three CCRAs over time is presented in Table 2.1 below, followed by discussion of a number of key updates of relevance in CCRA3.

**Table 2.1** Evolution of the CCRA method over time.

	<b>CCRA1</b>	<b>CCRA2</b>	<b>CCRA3</b>
<b>Objective and aims</b>	Quantification of risks / opportunities (impacts)	Assessment of risks / opportunities to inform adaptation	Assessment of risks / opportunities to inform adaptation and initial steps towards adaptive management
<b>Approach</b>	New analysis of all risks using standardised approach	Synthesis, supported by targeted new research	Synthesis, supported by targeted new research and inclusion of new climate projections
<b>Direct funding available*</b>	Approximately £3.5 million	Approximately £0.7 million	Approximately £1.8 million
<b>Method to assess risk / opportunities</b>	Quantitative or semi-quantitative impact assessment	3 step urgency framework	3 step urgency framework, with additional method development
<b>Identification of risks / opportunities</b>	Very wide initial review, with focus down on 100 or so most important	Initial list provided by Government and DAs, reviewed and extended based on evidence to ~55 risks and opportunities	Initial list provided by Government and DAs, reviewed and extended based on evidence to ~65 risks and opportunities
<b>UK climate Projections</b>	UKCIP02 and UKCP09	UKCP09	UKCP09, UKCP18, EuroCORDEX
<b>Global climate projections</b>	N/A	CMIP5	CMIP5, CMIP6, HELIX, UKCP18 global
<b>Economic analysis</b>	Indicative valuation of risks and opportunities	Not included	Indicative valuation of risks and opportunities, plus initial consideration of costs and benefits of further adaptation

\* It is highlighted that all three CCRA, but especially the synthesis assessments undertaken in CCRA2 and CCRA3, benefited from considerable levels of in-kind support. This included the time contribution of the CCC secretariat, as well as the inputs from contributor authors which were unpaid. The total costs of undertaking CCRA2 and CCRA3 is therefore much higher than shown in the table.

**Climate Science.** Since CCRA2, there has been the publication of new climate projections for the UK (Lowe et al., 2018; Murphy et al., 2018; Palmer et al., 2018). The CCRA3 Technical Report makes use of UKCP18 as far as possible, and bespoke analysis was carried out to help teams re-assess existing published evidence on future impacts (which is often based on UKCP09) in light of the new projections (see Chapter 1: Slingo, 2021). However, the Technical Report also draws on scenarios and studies that are not based on UKCP18 in order to ensure evidence is drawn from the widest possible base of research.

**Identification of risks and opportunities.** There are a very large number of potential risks and opportunities from climate change in the UK, indeed, the CCRA1 Evidence Report (HRW, 2012a) identified almost 1,000 of these following a series of stakeholder workshops to come up with a ‘long list’. This was then reduced down to the most important 100 or so based on a set of evaluation criteria. The approach adopted in CCRA3 is the same as the second CCRA (CCC, 2016) and focuses on the most important risks and opportunities as identified by the UK Government and devolved administrations, with some additions from the Technical Report authors and inputs from stakeholder workshops. This approach is therefore selective (rather than comprehensive). Although driven by the end user, this approach to risk selection runs a risk that some risks or opportunities (including unknowns) are poorly addressed, though CCRA3 has paid greater attention to the consideration of low-likelihood, high impact scenarios and events than previous CCRA3s (see later section).

**Consideration of Adaptation.** The role of the CCRA3 Technical Report – as part of the analysis of urgency - is to assess whether current and planned adaptation is managing risks and opportunities, and what adaptation gaps might be present. For the CCRA, an adaptation gap is considered to exist if risks (or opportunities) are not being managed (see section 2.7). This provides a clearer sense of where action is most urgently needed. Following a specific request from Government, a greater emphasis is given in CCRA3 to identifying where adaptation action is likely to be most ‘urgent’ between 2022 and 2027. This includes an indicative analysis of what form this additional adaptation could take, and possible costs and benefits, while noting it is not the role of the CCRA3 Technical Report to identify adaptation policies or make recommendations.

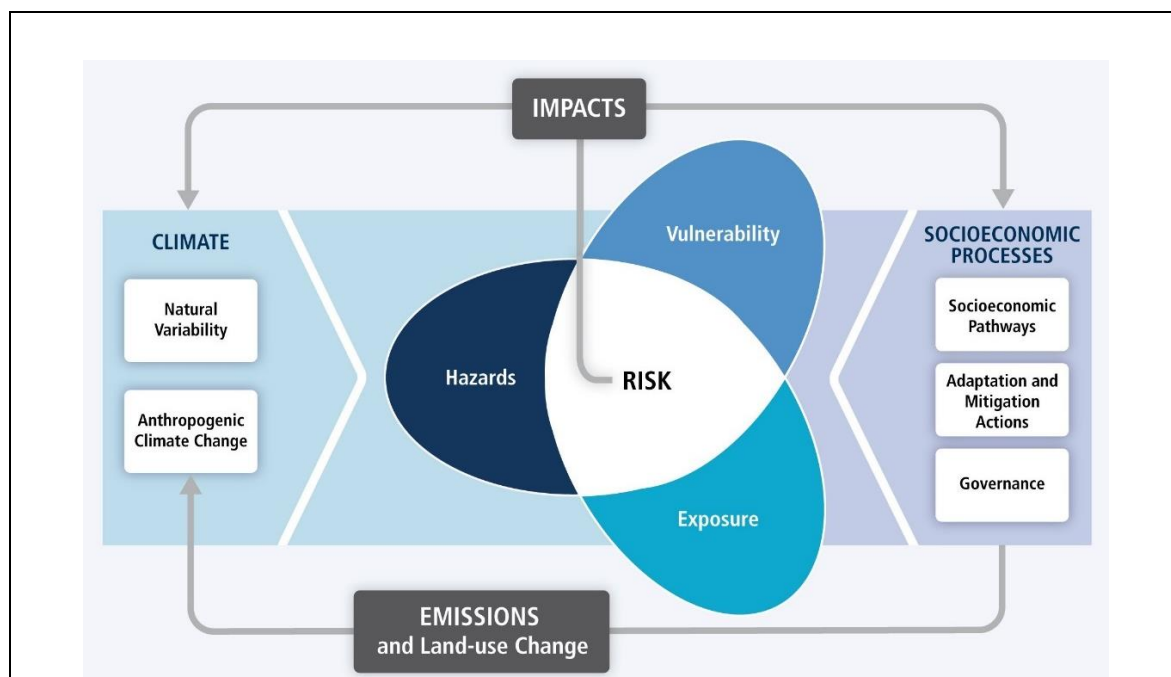

**Net Zero.** During the time period that the CCRA3 was being undertaken, the UK Government adopted a Net Zero greenhouse gas emissions target, as an amendment in the Climate Change Act. The Scottish Government committed to a target of Net Zero emissions of all greenhouse gases by 2045 and the Welsh Government has announced a 95% reduction in greenhouse gas emissions by 2050 with an ambition to reach Net Zero. This has important implications for future socio-economic scenarios and mitigation-adaptation linkages. To respond to this, an additional analysis was included in the second round of the CCRA3 evidence analysis. This undertook an initial analysis on the possible influence of climate risks on Net Zero measures, and considered mitigation-adaptation linkages.

### 2.1.2 Key Terms

In the context of the CCRA3 Technical Report, ‘risks’ are defined in line with the climate change literature (IPCC, 2014a), i.e. the potential for adverse consequences of climate-related hazards, based on their likelihood of occurrence, and taking account of exposure and vulnerability. In CCRA3, the term ‘risk’ is used to identify negative consequences from climate change, and the term ‘opportunity’ to identify positive consequences. A full glossary has been developed for CCRA3 and a number of the key terms are presented in Box 2.1. This draws primarily on the IPCC 5<sup>th</sup> Assessment Report (AR5) Core Concepts (IPCC, 2014a), the IPCC Glossary (IPCC, 2014b) and the IPCC Special Report on Global Warming of 1.5 °C (SR1.5) (IPCC, 2018b), but with additions on the new elements introduced in CCRA3. It has been reviewed and agreed by the CCRA3 technical team, peer reviewers and Government stakeholders.

**Box 2.1** Key concepts and terms used in CCRA3.

The main definitions in CCRA3 draw on the IPCC 5<sup>th</sup> Assessment Report (IPCC, 2014b) and the IPCC core concepts (IPCC, 2014a) and key terms are summarised below.

**Box 2.1 Figure 1.** Core Concepts of the IPCC 5<sup>th</sup> Assessment Report WG II. Reproduced from IPCC, 2014a.

**Risk** - The potential for adverse consequences where something of value is at stake and where the occurrence and degree of an outcome is uncertain. In the assessment of climate impacts, the term risk is often used to refer to the potential for adverse consequences of a climate-related hazard on lives, livelihoods, health and well-being, ecosystems and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure. Risk results from the interaction of vulnerability (of the affected system), its exposure over time (to the hazard), as well as the (climate-related) hazard and the likelihood of its occurrence. Source IPCC SR1.5. Note that in CCRA3, the term risk is used for negative consequences (i.e. threats).

**Opportunity** - The potential for a beneficial consequence, as a result of a changing climate (the propensity to be beneficially affected). Source: CCRA3 Method Chapter Authors.

**Exposure** - The presence (of people; livelihoods; species or ecosystems; environmental functions, services, and resources; infrastructure; or economic, social, or cultural assets) in places and settings that could be adversely affected. IPCC, AR5.

**Vulnerability** - The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt. Source IPCC, AR5.

**Hazard** - The potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, ecosystems and environmental resources. In the IPCC, hazard refers to climate-related physical events or trends. Source IPCC AR5.

**Impacts** - Effects on natural and human systems of extreme weather and climate events and of climate change. Impacts generally refer to effects on lives, livelihoods, health status, ecosystems, economic, social, and cultural assets, services (including environmental), and infrastructure due to the interaction of climate changes or hazardous climate events occurring within a specific time period and the vulnerability of an exposed society or system. Impacts are also referred to as consequences and outcomes. Source IPCC AR5.

**Adaptation** - The process of adjustment to actual or expected climate and its effects. In human systems, adaptation seeks to moderate or avoid harm or exploit beneficial opportunities. In some natural systems, human intervention may facilitate adjustment to expected climate and its effects. Source IPCC, AR5. This includes: Incremental adaptation - Adaptation actions where the central aim is to maintain the essence and integrity of a system or process at a given scale. Transformational adaptation - Adaptation that changes the fundamental attributes of a system in response to climate and its effects. Source IPCC AR5.

**Autonomous adaptation** - IPCC AR5 defined this as adaptation in response to experienced climate and its effects, without planning explicitly or consciously focused on addressing climate change (spontaneous adaptation). However, CCRA3 does not use the term autonomous adaptation. Instead, it considers two elements: reactive adaptation, i.e. a response to the changing climate experienced rather than a pro-active planned approach, as well as non-governmental planned adaptation (i.e. anticipatory adaptation undertaken by other organisations, e.g. private sector).

**Resilience** - IPCC AR5 defines as: the capacity of social, economic and environmental systems to cope with a hazardous event or trend or disturbance, responding or reorganizing in ways that maintain their essential function, identity and structure while also maintaining the capacity for adaptation, learning and transformation. However, the term resilience is now used very widely, in different ways, and as a consequence in CCRA3 we try and avoid the term due to the lack of a commonly applied definition. The exception is where it is used in existing Government policies, or in plans or actions as stated by the private sector or other groups, noting in such cases the specific definition should be included.

**Adaptation pathway** - A generic term that involves the analysis of adaptation options over time to changing risk levels. This term has been applied in a number of different ways, which include: i): Adaptation roadmaps or pathway frameworks, which consider portfolios of adaptation that change over time, to allow analysis of the timing and sequencing of adaptation and identify priorities; ii) Adaptive management, which is an iterative cycle of monitoring, research, evaluation and learning, i.e. a process, that is used to improve future management strategies (also called iterative risk management); iii) Dynamic adaptation route-maps, which focus on decision making under uncertainty and identify adaptation tipping points (or turning points), the point at which a particular action is no longer adequate for meeting the plan's objectives, that act as triggers for a change in adaptation. Source: CCRA3 Method Chapter Authors.

**Socioeconomic scenario** - A scenario that describes a possible future in terms of population, gross domestic product, and other socioeconomic factors relevant to understanding the implications of climate change. Source, IPCC AR5.

**Lock-in** - Early actions or decisions that involve long lifetimes or path dependency, which will potentially increase future risk or vulnerability and that are difficult or costly to reverse later (irreversibility). This can be from a 'business-as-usual' action or decision, from a lack of an action or decision, or from a maladaptive action or decision. Source: CCRA3 Method Chapter Authors.

## 2.2. Developments in the CCRA3 Methodology

The UK Climate Change Act (2008) set out the requirement to complete a Climate Change Risk Assessment (CCRA) every five years, followed by a National Adaptation Programme. This repeat cycle provides the opportunity to review and learn, and thus iteratively improve each CCRA (and subsequent NAP). In line with this, a number of methodological updates have been included in this CCRA Technical Report. These improvements have drawn on the lessons from CCRA2, as well as changing practices on risks and adaptation assessment from the literature. Alongside this, there was the publication of UKCP18 and a new set of CCC commissioned research was published. These developments are set out in this section.

### 2.2.1 Evaluation and Lessons from CCRA2

Following the first CCRA, a number of formal evaluations of the Evidence Report were undertaken (Wilby, 2012; HRW, 2012b; Watkiss and Hunt 2012). These provided recommendations that were used in the methodology update and subsequent implementation of CCRA2 (see Table 2.1). There were also several academic reviews of CCRA1 (Tangney, 2017; Tangney and Howes, 2016).

There was not a formal evaluation of the CCRA2 Evidence Report. However, the CCC produced a lessons report, based on feedback from its Adaptation Committee, as well as Evidence Report authors and the Customer Group of the CCRA. This concluded that distilling the evidence into urgency scores was an effective way to communicate the results in a meaningful way for Government. It also reported that the governance arrangements worked well, i.e. the use of an IPCC-like synthesis approach, with lead contributors and a larger group of contributing authors, overseen by the CCC's Adaptation Committee, acting to coordinate the whole project with independence from Defra. The approach, combined with a two-stage peer and stakeholder review process, delivered an Evidence report that was authoritative and usable. However, the lessons report identified that the success of the project relied heavily on goodwill (given that most authors were not paid), and that the length of the process created challenges. It was also difficult to differentiate risks by scenario (i.e. between the 2°C and 4°C global temperature increase by 2100, relative to pre-industrial), due to the evidence available and the resource constraints. There was also insufficient information on common socio-economic scenarios for the UK. The synthesis approach also made it difficult to assess the magnitude of risks with little evidence or inconsistent assumptions from different evidence sources. There was considered to be insufficient cross-sectoral analysis in the report. Finally, some chapters struggled to get buy-in or material from Government Departments, indicating a need for an improved Government review process. There has also been some academic literature that has compared and evaluated CCRA1 and CCRA2 and made suggestions on future risk assessments (e.g. Howarth et al., 2018), particularly on some aspects of method, operationalisation and better communication.

The CCC consulted with Government (the key users of the Evidence Report), to get feedback on improving the CCRA method. This led to a CCRA3 Requirement Document, produced by Defra and the devolved administrations, and also represented the views of other government departments as fed in using a consultation process. This included the following key requests for CCRA3:

- To inform the adaptation plans of the UK Government and the devolved administrations, and to help this, make the outputs and key messages more accessible (e.g. greater use of infographics, guidance on entry points for outputs, shorter, crisper and less technical summary reports);
- To use a more systems-based approach than CCRA2 to take better account of interdependencies and interactions;
- To take account of new evidence on climate projections (namely UKCP18, most of which was published in November 2018, with a further set of high-resolution projections published in September 2019);
- To consider different future global warming scenarios, including those associated with a 2°C and a 4°C increase in global mean temperature by the end of the century, relative to pre-industrial.
- To use the urgency framework developed for CCRA2, refining it to identify a smaller number of specific priorities for the next five-year period;
- To avoid recommendations about the risk appetite for addressing risks, or on how to adapt, since those are policy or operational decisions. However, where appropriate, and for consistency with CCRA2, to include consideration of some adaptation scenarios that go beyond planned adaptation.
- There was also a subsequent request, as part of discussions with Defra and the DAs, to assess risks and opportunities in monetary terms, and to consider the indicative costs and benefits of adaptation, i.e. to include more economic analysis than in CCRA2.

As part of the CCRA3 methodology development, a rapid evaluation of CCRA2 was also undertaken by the methodology chapter team. This found that the smaller number of risks in CCRA2 (56) allowed a more focused assessment. However, while the use of literature review and synthesis did provide a good evidence base, there was not the same quantitative information of magnitude as generated in CCRA1, and less direct comparability between risks, although this was not considered to be detrimental to the final Evidence Report. The use of the urgency framework was considered a particularly useful addition, as this focused the evidence towards a policy-first approach (Ranger et al., 2010) that informs adaptation – as compared to a science-first approach that focuses on the climate projections and impacts (as in CCRA1). The success of CCRA2 was particularly noteworthy given the much lower resources available than for CCRA1.

Alongside this there was also some analysis of the uptake and use of the CCRA2 Evidence Report in policy, i.e. in the subsequent five-year adaptation policy period and the 2<sup>nd</sup> National Adaptation Programme for England (Defra, 2018), as well as the Adaptation Programmes of the DAs. The CCC Adaptation Progress Report (CCC, 2019a), and supporting research (Watkiss et al., 2019) found that the coverage of the risks and opportunities from the CCRA2 Evidence Report in the 2<sup>nd</sup> NAP (Defra, 2018) was partial. A similar finding (Watkiss et al., 2019) was found for the use of CCRA2 Evidence material in the UK Government 25 Year Environment Plan (25 YEP) (HMG, 2018), which set out the long-term strategy for the environment, including climate change. For the latter, the analysis identified that there was not a systemic analysis to integrate climate risks across the 25YEP objectives and goals (i.e. a climate adaptation mainstreaming exercise).

CCRA2 undertook a very high-level assessment of the benefits of further action (step 3 of the method), consistent with the resources available. The reviews above identified that in many cases, this step identified future research priorities. A greater focus on potential interventions, rather than

research gaps, was therefore identified to offer more relevant information for the development of planned adaptation by the Government.

Finally, as noted above, after CCRA1 a number of formal evaluations were undertaken. This process step was not repeated in the same depth after CCRA2, reducing the opportunity for learning. A stronger component of evaluation and learning was therefore identified, to be undertaken after the publication of CCRA3.

## 2.2.2 Lessons from other national climate risk assessments and academic literature

The UK is not the only country undertaking climate risk assessments. Most European countries have undertaken these types of climate risk assessments and have published national adaptation plans, and globally, many countries are undertaking similar exercises as part of the UNFCCC National Adaptation Plan process. These other assessments provide potentially valuable lessons, and a rapid review of other national risk assessments was undertaken to help inform CCRA3. The review concentrated on those countries that have already undertaken multiple assessments (and thus include learning cycles). Some of the key findings are summarised in Box 2.2. The lessons from this review were used to update the CCRA3 method, so as to reflect current good practice (see section 2.3).

There are also other climate change risk assessments at different scales emerging in the UK, such as the recent climate risk and opportunity assessment for Glasgow City Region (CRC, 2019) and the analysis of the Climate Risk Assessment by Kent County Council on behalf of the Kent Climate Change Network. This highlights that national level assessments can cascade down to local risk assessment, either using similar approaches or assessing what the national level implications mean for the local area.

### **Box 2.2** Review of other Climate Change Risk Assessments.

A number of other national climate change risk assessments were rapidly reviewed. The focus was to identify additional methodological aspects as compared to CCRA2, and look for lessons on application in national risk assessment. Some key insights are highlighted below that were considered particularly relevant.

The US 4th National Climate Assessment (USGCRP, 2018) is a mandated risk assessment, which is delivered every four years, with the requirement to analyse the effects of global climate change (on the USA). The assessment is an extremely comprehensive analysis, and has benefited from several successive assessment cycles. It provides some useful lessons on how to raise interest in climate risks in a challenging climate policy landscape. Methodologically, it has many aspects that are similar to CCRA, but the most recent analysis also refined the goal to focus on key messages using a series of questions:

- What do we value? What is at risk?
- What outcomes do we wish to avoid with respect to these valued things?
- What do we expect to happen in the absence of adaptive action and/or mitigation?
- How bad could things plausibly get?
- Are there important thresholds or tipping points in the unique context of a given region, sector, and so on?

The aim was to address the overarching question of ‘what keeps you up at night?’ There was also a stronger focus on:

- Impacts and losses on the economy;
- Extreme impacts (Impacts from changes in extreme statistics of key climate variables) that are less likely but have severe consequences;
- Communicating cascading effects among and within complex systems;
- Quantification of risks that could be avoided by taking action.

The Netherlands has been one of the leaders in climate risk and adaptation planning globally. The most recent National Climate Adaptation Strategy 2016 (NAS, 2016), while it has different objectives to the UK CCRA, does include a risk assessment and this uses four diagrams (‘Hotter’, ‘Wetter’, ‘Drier’ and ‘Rising Sea Level’) to visualize the effects of climate change within nine sectors: water and spatial management; nature; agriculture, horticulture and fisheries; health and welfare; recreation and tourism; infrastructure (road, rail, water and aviation); energy; IT and telecommunications; public safety and security. From this it sets out six climate effects which call for immediate action to be identified. The diagrams provide a useful way of trying to communicate climate information and have been reviewed alongside other international examples to help design the CCRA3 summary products.

There is also a literature on climate change risk assessment associated with the large flows of finance being spent internationally on adaptation, which provides valuable new insights. In 2017/18, global public finance flows for adaptation were estimated at US\$30 billion (CPI 2019). A very large proportion of this (\$7.4 billion: MDBs, 2017) was financed by the large multi-lateral development banks (MDBs) and International Financial Institutions (IFIs) including those in Europe. Of high relevance, these organisations have implemented climate risk management systems (CRMs) as part of their due diligence processes, and they undertake routine climate change risk assessment of investments, especially for infrastructure (MDBs, 2017). These assess the level of climate risk during the project appraisal cycle, and if needed, include adaptation (resilience) measures. They provide an existing and applied evidence base on processes and implementation practice for climate risk analysis of major investments, as well as lessons on improving risk assessments over time (ADB, 2020) that have relevance for national assessments.

The academic literature on climate risk assessment and adaptation has also developed considerably since the last CCRA. A rapid review to inform CCRA3 identified a number of relevant themes that were subsequently incorporated where possible into the CCRA3 method:

- A greater focus was included to encourage iterative risk management (Jones et al., 2014) in CCRA3 (also called adaptive management), to help prioritise and sequence adaptation over time. These approaches are sometimes called adaptation pathways, though this term is used for several different approaches (see key terms Box 2.1).
- The lessons from new decision support approaches for adaptation, including decision making under uncertainty (DMUU), were included in CCRA3. While most of the formal DMUU methods are more applicable at the project scale, rather than at the national level, the concepts that these approaches advance, e.g. robustness, diversity, flexibility, learning, and minimizing regret (Watkiss et al., 2014), are useful to help identify potential additional adaptation action.
- An additional method component (in Step 2 on adaptation) was added to recognise that there are barriers (constraints) to adaptation (for both risks and opportunities) (Klein et al., 2014), and

that addressing these barriers is important for implementation of adaptation. This also aligns to the traditional policy appraisal framework in UK Government (set out in the UK Green Book, HMT, 2018), and can help the subsequent justification for adaptation policy and programming.

- There was a greater focus on the consideration of climate risks in private sector decisions in CCRA3, reflecting developments on the financial reporting of climate risks. This aligns to the initiatives of the Task Force on Climate-related Financial Disclosures (TCFD, 2017) and the Network for Greening the Financial System (NGFS, 2019). These frameworks identify physical climate risks (the risks which are the focus of CCRA3) as well as transition risks (associated with policy or technology change as the world reduces greenhouse gas emissions, which are not considered in CCRA3). There has also been a recent recognition of liability risks, which arise from people or businesses seeking compensation for losses they may have suffered from physical or transition risks (BoE, 2018). These initiatives are likely to stimulate greater interest from the private sector in the CCRA3 results. In response, the CCRA3 Expert Advisory Panel strengthened private sector involvement and interest in CCRA3, though the main audience for the Independent Assessment (including the Technical Report) remains Government.
- Reflecting the government request, the CCRA3 method considered, in indicative terms, the monetary valuation of risks and opportunities (presented in a separate economic report), and the indicative costs and benefits of further adaptation (included in Step 3).
- The CCRA3 method and its implementation have also adopted a stronger emphasis on co-design and co-production - i.e. the participatory development of the project with stakeholders (end-users) (Hegger et al., 2012; Beier et al., 2016) than previous cycles. This drew on recent review work which has identified the key success factors for co-production for climate change and adaptation (COACCH, 2018). Additional co-production activities were undertaken as part of the Technical Report chapter research and analysis, while noting there were some limits due to the need to respect the governance arrangements for CCRA3, i.e. to produce a report that is independent of Government while at the same time undertaking co-production of research with Government as a key end-user.
- There is growing recognition that climate risks will not be distributed evenly (among groups as well as places) (JRF, 2016) and thus additional consideration of distributional effects and inequalities was included.
- There is more focus on the potential synergies and trade-offs between adaptation and mitigation (OECD, 2017; IPCC, 2018a), and this became even more relevant area during the time-period of CCRA3 with the announcement of Net Zero targets and analysis (CCC, 2019b).
- Finally, there is a growing focus in the literature on the need for transformational adaptation (Field et al., 2014; Lonsdale et al., 2015; CRC, 2020), which requires fundamental change, as compared to incremental adaptation (see Box 2.1) and this is reflected in the final method step and greater linkages to CCRA4.

### 2.2.3 New Climate Science and UKCP18

A new, comprehensive set of state-of-the-art climate projections for the UK were released in November 2018 by the Met Office and its partners (Lowe et al., 2018; Murphy et al., 2018; Palmer et al., 2018), commissioned by Defra. The UKCP18 projections provided important new information of relevance to CCRA3 and were taken into account as much as was practically possible. For example, they were used in the supplementary analysis undertaken by the research projects.

A key part of the CCRA3 methodology was to take advantage of the new UKCP18 information, while acknowledging that due to the timing of release, it has not fed into the risk and opportunity literature. Reflecting this, the Technical Report has drawn on scenarios and studies that are not based on UKCP18 in order to ensure evidence is drawn from the widest possible base of research.

Although a number of studies have already been carried out using UKCP18, most of the literature on future UK climate risks assessed in CCRA3 is inevitably based on the previous set of climate projections, UKCP09 (Murphy et al., 2009). It is noted that some climate risk-related quantities in UKCP18 are quite different to those in the previous projections, while others are similar (see Chapter 1: Slingo, 2021). It has been important to assess where these differences are extensive enough to affect the advice previously provided by the CCRA, and thus affect CCRA3 findings.

UKCP18 contains some projection tools that are similar in nature to those in UKCP09, such as the probabilistic projections, the regional climate model projections and the sea-level rise projections. As an update from UKCP09, UKCP18 includes the more recent emissions scenarios linked to the Representative Concentration Pathways (RCPs). The probabilistic projections considered four RCP scenarios, ranging from RCP2.6 (which is consistent with extensive mitigation of emissions) through to RCP 8.5 (which has future emissions considerably higher than pathways considered consistent with current worldwide energy policies). The intermediate scenarios RCP4.5 and RCP6.0 were also included: these are within the range of possible emissions futures considered consistent with current worldwide policies, and RCP6.0 is used to define the higher climate change scenario used in the CCRA3 Technical Report (see Box 2.5 and also the Introduction chapter: Betts and Brown, 2021).

An important feature of both the UKCP18 and UKCP09 probabilistic projections that is different to most other projections with General Circulation Models of climate is that they are driven by scenarios of emissions scenarios rather than concentrations. For example, the widely-used models in the 5<sup>th</sup> Coupled Model Intercomparison Project (CMIP5) apply the RCPs as pathways of greenhouse gas concentrations in the atmosphere, but in contrast, UKCP18 uses emissions scenarios aligned to the RCPs but calculates its own concentration pathways accounting for uncertainties in carbon cycle feedbacks to be explored and quantified. The latter approach results in a range of concentration pathways, most of which rise faster than the standard RCP concentration pathways. This is an important influence on the differences in projected rates of warming between UKCP18 and CMIP5 (Murphy et al., 2018).

As a further advance from UKCP09, information from the UKCP18 probabilistic scenarios has been used to quantify the effects of natural climate variability on the spread of future outcomes (Murphy et al., 2018).

As well as the UK and global probabilistic projections, UKCP18 provided a 28-member perturbed parameter ensemble (PPE) of global (60km resolution), and PPEs of regional (12km) and local (2.2km) projections over UK land areas, driven by a range of concentration pathways arising from the standard RCP8.5 emissions scenario. The 12km resolution of the regional projections is higher than the 50 km resolution of the equivalent projections in UKCP09, and in some cases these project larger changes in weather extremes such as heavy precipitation – a comparison of this was carried out in support of the CRA3 Technical Report (Johns et al., 2021). The high-resolution (2.2km) Convective Permitting Model used in the local projections has been shown to simulate extreme

precipitation events more realistically than lower-resolution models so the changes in the local projections provide further important context for the assessment, as discussed in Chapter 1.

60km-resolution projections were also provided for global warming levels of 2°C and 4°C global warming above pre-industrial, and for the RCP2.6 emissions scenario (Gohar et al., 2018).

UKCP18 also includes probabilistic projections with one of the same emissions scenarios (SRES A1B) as used in UKCP09, so that a direct comparison can be made with previous probabilistic projections (Murphy et al., 2018). The method used for assessing the implications of the new regional climate projections in the UKCP18 projections for conclusions derived from UKCP09-based regional projections is described in Box 2.4.

Like UKCP09, UKCP18 also includes marine projections including the rise in long-term average sea level, changes in short-term extreme water levels from storm surges, and changes in wave height (Palmer et al., 2018). Since these were developed in parallel with the new climate modelling system used for the UKCP18 land projections, the marine projections used existing climate projections from CMIP5. Although this inevitably results in potential inconsistencies between the UKCP18 land and marine projections, this does not pose a difficulty for CCRA3 as the Technical Report already draws on literature from a wide range of very different sources and has applied a framing of future projections which groups these together appropriately.

## 2.2.4 New climate science: low-likelihood, high-impact scenarios and events

It is important for a risk assessment to consider high-impact outcomes even if they are considered to be of low likelihood. This includes responses of the climate system outside of the ranges considered “likely”, and also potential abrupt climate changes and the passing of “tipping points” in the Earth System (see Chapter 1: Slingo, 2021). Examples of the former include high values of equilibrium climate sensitivity or carbon cycle feedbacks strength which are facilitated by the use of probabilistic projections. Regarding climate tipping points, also known as earth-system tipping points, and sometimes as climate tipping elements (Lenton et al., 2008; Lenton et al., 2019), some of these are now included in mainstream climate projections and other studies related to these, but many are still not.). Nevertheless, they are increasingly recognised as a very important component of climate change risk assessment, and modelling and theoretical work has been performed to explore them outside of the mainstream climate projections.

These earth system climate tipping points elements were not included in depth in CCRA1 or CCRA2, and this was considered an important omission. They have therefore been included in CCRA3. Some are included either explicitly or implicitly in the UKCP18 projections: the marine report considers the implications of marine ice shelf instabilities which could lead to more rapid sea level rise, and the probabilistic land projections include uncertainties in carbon cycle feedbacks based on a model which simulates die-back of the Amazon forest in some of its simulations (Boulton et al., 2017). The high-emissions RCP8.5 scenario can also serve as a proxy for climate projections with much stronger carbon cycle feedbacks than in current Earth System Models, which could be used to represent the effects of permafrost thawing and other biospheric sources of carbon dioxide or methane emissions. A scenario of shutdown of the Atlantic Meridional Overturning Circulation (AMOC) has also been examined with a version of the main climate model used in UKCP18 (Jackson et al., 2015), and although this is not included in the UKCP18 projections themselves, it has been used for assessing

some impacts on the UK (Ritchie et al., 2020). The implications of some of these has been considered for a limited number of risks, and an additional study was performed for CCRA3 to examine these and other tipping points from a UK perspective (Hanlon et al., 2021). Since this showed that information on the implications of other climate tipping points for UK climate risks remains limited, it was not possible to include an assessment of tipping points at the level of all individual risks and opportunities. Instead, they are considered through a separate cross-cutting analysis in each chapter following the discussion set out in Chapter 1 (Slingo, 2021).

## 2.2.5 Additional Commissioned Research

Following the CCRA2 Evidence report, an evidence gap analysis was commissioned by the CCC. This identified over 200 evidence gaps. Following a stakeholder engagement period in 2016 – 2018, the CCC commissioned six research projects to inform the CCRA3 Technical Report, using funding provided by Defra, the devolved administrations and research councils (NERC, ESRC and EPSRC). These projects were:

1. Updated projections of future water availability for the UK (HRW, 2020);
2. Updated projections of future flood risk for the UK (Sayers et al., 2020);
3. Understanding how behaviours can influence climate change risks (Power et al., 2020);
4. Climate driven threshold effects in the natural environment (Jones et al., 2020);
5. Interacting risks (WSP, 2020);
6. A consistent set of socioeconomic projections dimensions for the CCRA3 Evidence Report research projects (Cambridge Econometrics, 2019).

These projects have fed into CCRA3 in a number of ways. The flood risk and water availability studies provided updated quantified risk estimates for CCRA3, using the new UKCP18 products. They also used the new socio-economic projections provided by the sixth research project. Some of the other studies have provided information of relevance to the update methodology in CCRA3. The threshold study helped to provide information for the new pathways thinking in CCRA3, while the interacting risks project was used to help assess the interacting and cross-cutting risks (which are undertaken for each risk/opportunity in the chapters in CCRA3, rather than as a separate cross-cutting chapter as in CCRA2).

Work was also commissioned in support of the CCRA3 Technical Chapters to assess the impacts of climate change on agricultural land use and associated greenhouse gas emissions (Mancini et al., 2021), again using UKCP18 projections. Further additional work was carried out by the research community on implications of climate change for wildfire risks in the UK (Belcher et al., 2021). This had been identified as an area where the evidence base had not advanced substantially between CCRA1 and CCRA2.

The results of these studies and the CCRA3 research described in sections 2.2.3 and 2.2.4 are included throughout the Technical Report chapters and referenced as such.

## 2.3 The CCRA3 Approach: Using Risk Assessment to Inform Adaptation

### 2.3.1 The Framework for CCRA3

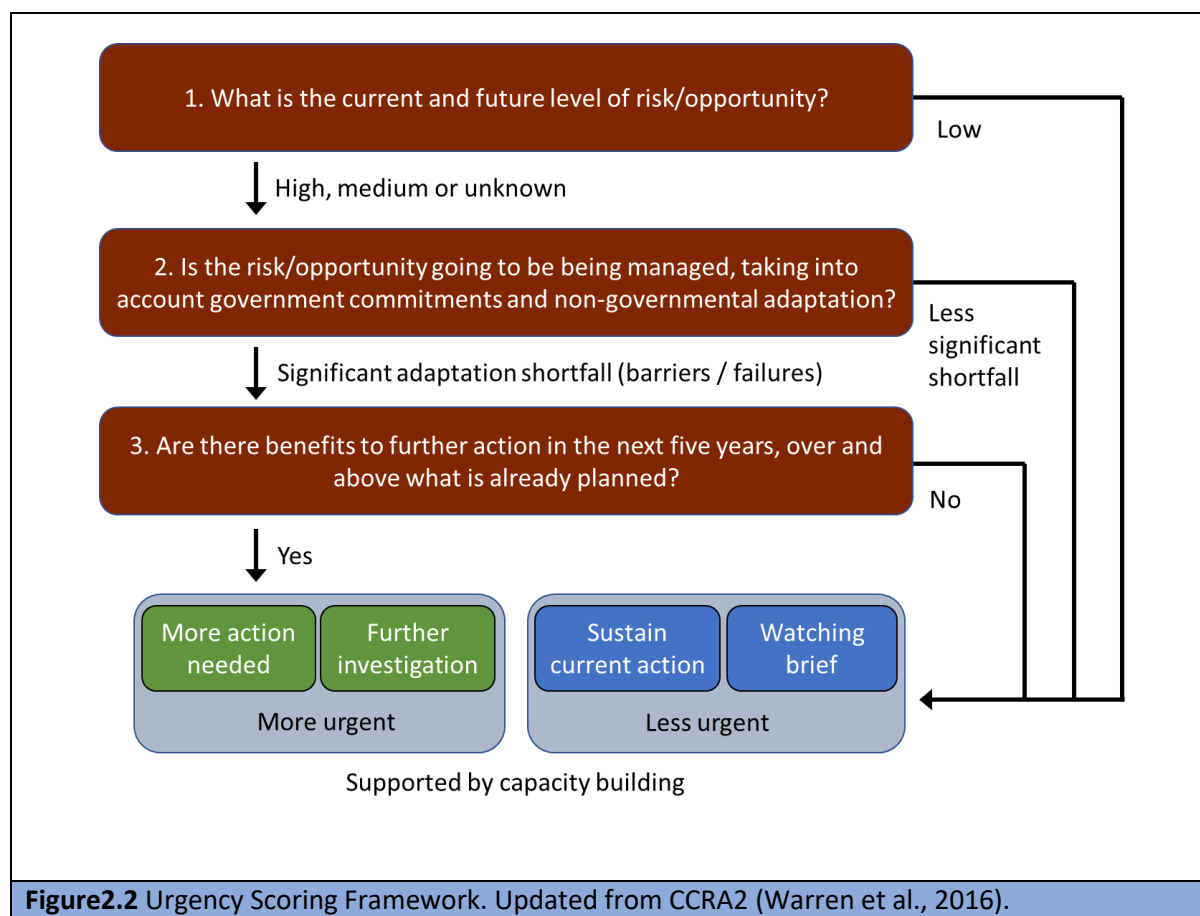

The CCRA3 Evidence method is based on the prioritisation of risks and opportunities, using an analysis of urgency. This seeks to address the issue of ‘where is action needed most urgently over the next five-year period’? This is complemented by a second framework (applied in Step 3) that helps to identify early adaptation priorities to respond to the identified risks and opportunities, i.e. that seeks to address the issue of ‘what type of action is most urgently needed?’

#### 2.3.1.1 Establishing urgency

The analysis of the urgency of risks and opportunities was undertaken in CCRA2 through an urgency framework (Warren et al., 2016). This high-level framework has been carried over into CCRA3, with minor refinements. It prioritises risks and opportunities using three questions:

1. What is the current and future level of risk/opportunity?
2. Is the risk/opportunity going to be managed, taking into account Government commitments and other non-Government adaptation?
3. Are there benefits to further action in the next five years, over and above what is already planned?

These three questions are shown within the decision flow diagram in Figure 2.2.

#### 2.3.1.2 Identifying possible priorities for early adaptation

The CCRA Technical Report aims to provide evidence to inform adaptation. Following from the urgency diagram above, it seeks to provide additional information on what type of adaptation action

might be beneficial in a case where more action is needed. This is influenced by the type of decision, noting that for many risks and adaptation responses, there is a need to address the challenge of deep uncertainty, i.e. where the probability of risks is not known (Hallegatte et al., 2012). An initial adaptation framework was set out in CCRA2 (Warren et al., 2016; Warren et al., 2018). This built on a well-established literature and existing frameworks for identifying early adaptation priorities, using a portfolio or ‘building block’ approach (drawing on Fankhauser et al. (1999); Ranger et al. (2010); Watkiss and Hunt (2011)). This framework has been updated in CCRA3, and identifies three main priorities for early adaptation activities, which are to:

- Address any current adaptation gap by implementing ‘no-regret’ or ‘low-regret’ actions<sup>1</sup> to reduce risks associated with current climate variability as well as building future climate resilience, or to enhance opportunities.
- Intervene to ensure that adaptation is considered in near-term decisions that have long lifetimes, such as major infrastructure developments, in order to avoid ‘lock-in’ (see key terms). This can include the use of decision making under uncertainty (DMUU) concepts (i.e. flexibility, robustness).
- Fast-track early adaptive management activities, especially for decisions that have long lead times or involve major future change, including planning, monitoring and research. This can enhance learning and allows the use of evidence in forthcoming future decisions, for either risks or opportunities.

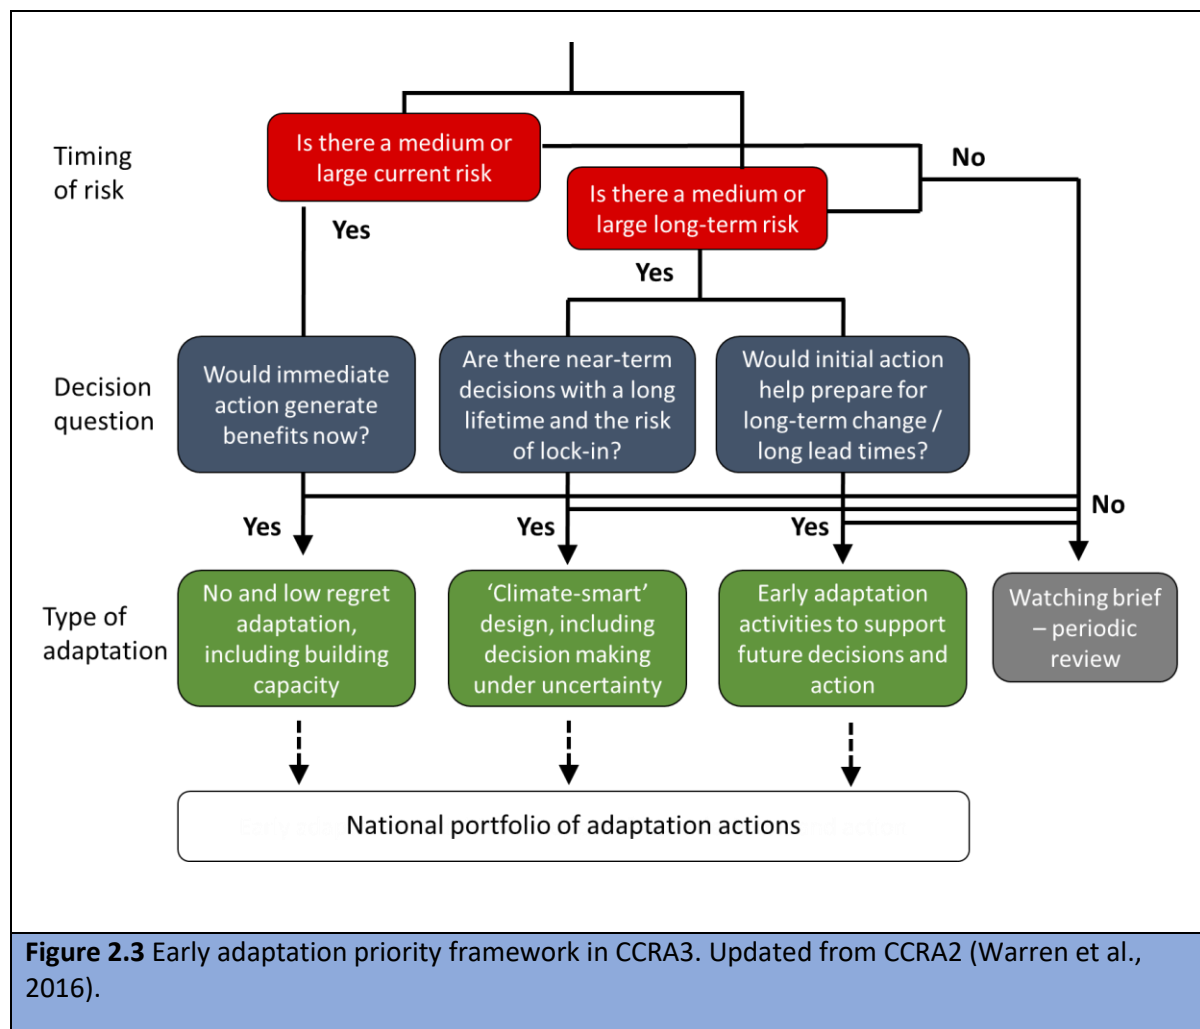

These are shown in the adaptation priority framework in Figure 2.3, along with the decision characteristics involved. It is stressed that at the national level, all three of these adaptation priorities or building blocks (shown in the green boxes) are needed, and this requires portfolios of interventions for each individual risk or opportunity. Indeed, the three activities above can be part of an overall adaptive management process or adaptation roadmap (see section 2.3.2).

The differences between the three ‘building blocks’ of early adaptation in Figure 2.3 are quite subtle, but important. Each involves a different combination of the time-scale of climate risks and the time period of the adaptation decision. On the left of Figure 2.3, there are some current decisions or actions that can be taken now to address current climate risks. These lead to an immediate benefit. An example is to improve weather and climate services to reduce current weather-related impacts from heatwaves. Moving to the centre of Figure 2.3, there are some near-term decisions which will be exposed to future climate change risks, and there is a one-off opportunity to adapt now. For example, to change the design of a major new infrastructure project (e.g. a major bridge or hydroelectric-power plant) to make them more resilient to future climate change, noting later major retrofits could be expensive or impossible. Finally, on the right of Figure 2.3, there are some future decisions that may need to be implemented to address major climate change in the future. Some of these will take time to develop, and some will benefit from improved information and learning. In these cases, it makes sense to start planning now (especially if lead times are long or the potential for learning is large). The Thames Estuary 2100 project (Ranger et al., 2013) is such an example,

---

<sup>1</sup> No-regret adaptation is defined as options that ‘generate net social and/or economic benefits irrespective of whether or not anthropogenic climate change occurs’ (IPCC, 2014b). A variation of no-regret options are win-win options, which are options that have positive co-benefits, which could include wider social, environmental or ancillary benefits. These are differentiated from low-regret options, which may have low costs or high benefits, or low levels of regret, or may be no-regret options that have opportunity or transaction costs in practice.

where early planning and monitoring has been put in place now to prepare for the possibility that a new Thames Barrier might be needed in the long-term. The key point is that all of these involve some actions in the next five years, i.e. in the next NAP period.

This adaptation framework is applied in Step 3 of the urgency method (see Figure 2.2). However, a lesson from the review of CCRA2 was that this requires particular evidence to be gathered in Steps 1 and 2, to allow the subsequent application of the framework in Step 3. For this reason, additional information requirements (to inform adaptation) were added early in the CCRA3 method - this includes a greater emphasis on lock-in, thresholds, and adaptive management – and are discussed in the next section.

It is noted that while this methodology has been applied to all risks and opportunities in CCRA3, it is more challenging to apply this approach to international risks (Chapter 7: Challinor and Benton, 2021). Additional information on how this has been addressed is presented in that chapter.

This method was applied to all risks and opportunities, at the level of each of the four countries (England, Northern Ireland, Scotland and Wales) as set out in the CCRA3 Requirement Document. It is highlighted, however, that risks and opportunities vary across regions and populations. In practice, for adaptation decisions, greater dis-aggregation may be needed.

### 2.3.2 New focus areas in CCRA3

A number of additional developments – related to the frameworks above - are included in CCRA3. These encourage more adaptive management thinking in the CCRA, although there are limits to what is possible given that CCRA3 is a synthesis exercise, rather than new analysis of future impacts and adaptation. These are described briefly below.

#### 2.3.2.1 Risks of Lock-in

The first area that is given greater weight in CCRA3 is the risk of **lock-in**. The adaptation literature on lock-in has generally focused on decisions that ‘lock-in’ the potential for future climate change risks that are difficult or costly to reverse or change later (Fankhauser et al., 1999; Ranger et al., 2010; Fankhauser et al., 2013) and this term was included in CCRA2 (Warren et al., 2016). It is recognized that lock-in is an important issue for early action, and it has been considered in recent CCC progress reports (e.g. CCC, 2015; 2017; 2019a). The term lock-in has also appeared in the IPCC glossary for recent special reports (IPCC, 2018b), which defines it as *a situation in which the future development of a system, including infrastructure, technologies, investments, institutions, and behavioural norms, is determined or constrained (‘locked in’) by historic developments*. CCRA3 investigated these issues in more detail, with an updated literature review on lock-in, including a consideration of the use of the term in the mitigation literature (see Seto et al., 2016).

Based on this, a new definition was developed for the CCRA3 (see Box 2.1). This captures the relevant focus on lock-in that could arise in the next NAP period (i.e. the next five years or so) and relates to actions or decisions that could potentially increase future risk or vulnerability and that are also difficult or costly to reverse later (quasi-irreversibility / path dependency). This can be from i) action or decision taken that is business-as-usual’, ii) from a lack of an action or decision, or iii) from a maladaptive action or decision.

An example where business-as-usual actions or decisions could involve lock-in (i) is the building of new infrastructure, which has a long life-time. Where this does not consider future climate risks, this may experience large future climate impacts, and/or could be expensive or difficult to retrofit later. This could be large projects that do not consider future floods risks or building large numbers of houses that do not consider future overheating risk. It can also involve land-use decisions, as these tend to lock-in development patterns irreversibly, e.g. developing new areas that may become at risk under future climate related flooding. At the same time, lock-in could also include policy decisions associated with these investments (e.g. building standards or development policy) and even new policy or market based instruments that increase exposure, sensitivity or vulnerability. An example of (ii) could include a case where peatlands are not restored in the short-term, leading to further degradation that is irreversible, which removes its coping capacity to future climate shocks. It could also include a failure to manage other drivers of stresses, such as rising demand for water, that increase susceptibility to future climate change. Finally, examples of maladaptation (iii) could include a major investment today that involves a sunk cost for an adaptation measure that may not be needed, or implementing costly adaptation without considering uncertainty (noting also that lock-in may constrain future adaptation decisions). In the CCRA3 method, a decision that involves a potential risk of lock-in is given a higher magnitude score, and assigned a higher urgency score requiring action sooner.

### 2.3.2.2 Thresholds

The second area of greater focus in CCRA3 is around **thresholds**. These represent levels or states beyond which there is step-change in risks and which may necessitate much greater levels of adaptation (or even may reach the limits of adaptation, Klein et al., 2014). This draws on the literature on adaptation decision-making under uncertainty (DMUU) and adaptation pathways (e.g. Ranger et al., 2013; Dittrich et al., 2016). CCRA3 has included more adaptive management thinking, with a more explicit consideration of thresholds and the potential differences for these between 2 and 4°C pathways. In considering these elements, authors were asked to consider a number of different types of thresholds:

- **Biophysical thresholds.** Typical examples are the suitability or lethal threshold limits for crops, temperature thresholds for heat and daily mortality, or thresholds for heating or cooling demand. These thresholds are sometimes translated into current policy, e.g. the Heat Health Watch heat-wave temperature thresholds, or occupational temperature thresholds.
- **Engineering thresholds.** These are often associated with design standards and tolerance levels for various climate parameters, e.g. rail buckling temperature thresholds, maximum water flows for drainage channels etc.
- **Performance thresholds.** These thresholds are linked to the adaptation tipping points literature (also known as adaptation turning points) (Haasnoot et al., 2013; Werners et al., 2013), and they relate to points beyond which a particular action is no longer adequate for meeting a plan's objectives and a different adaptation option or strategy is required, including sometimes more transformational measures. These can include a wide range of types of thresholds, e.g. service levels, economic returns.
- **Policy thresholds.** These may be policy levels that are set to politically determined levels of acceptable risk or economic optimality, e.g. the use of 1 in 100 year level of flood protection, or policies that define unacceptable risks.

It is noted that for the first of these, there may be natural or intrinsic thresholds, which may be immutable. For the other three, these thresholds are often set by decision makers, and thus reflect policy choices.

The consideration of thresholds (particularly performance thresholds) has been used widely in the adaptation tipping points literature and adaptation pathways (see definition Box 2.1). However, these pathway approaches and threshold analysis are more often used at the project level, and there are challenges to implement them at the national level. Nonetheless, there is a value to exploring potential risk (or opportunity) thresholds, to help inform the CCRA3 and to encourage more pathway thinking. It is also highlighted that there is a separate literature on global (Earth System) thresholds (often called climate tipping points), discussed in section 2.6., which should not be confused with the thresholds or adaptation turning points discussed above.

### 2.3.2.3 Sequencing adaptation, adaptive management and transformational adaptation

While the focus of CCRA3 is to identify where further adaptation is needed in the next reporting period (to address priority risks and opportunities over the short, medium and long-term), these early priorities need to be seen as part of a longer-term **adaptive management process**, i.e. that encourages a cycle of evaluation, learning, and revision (of possible actions).

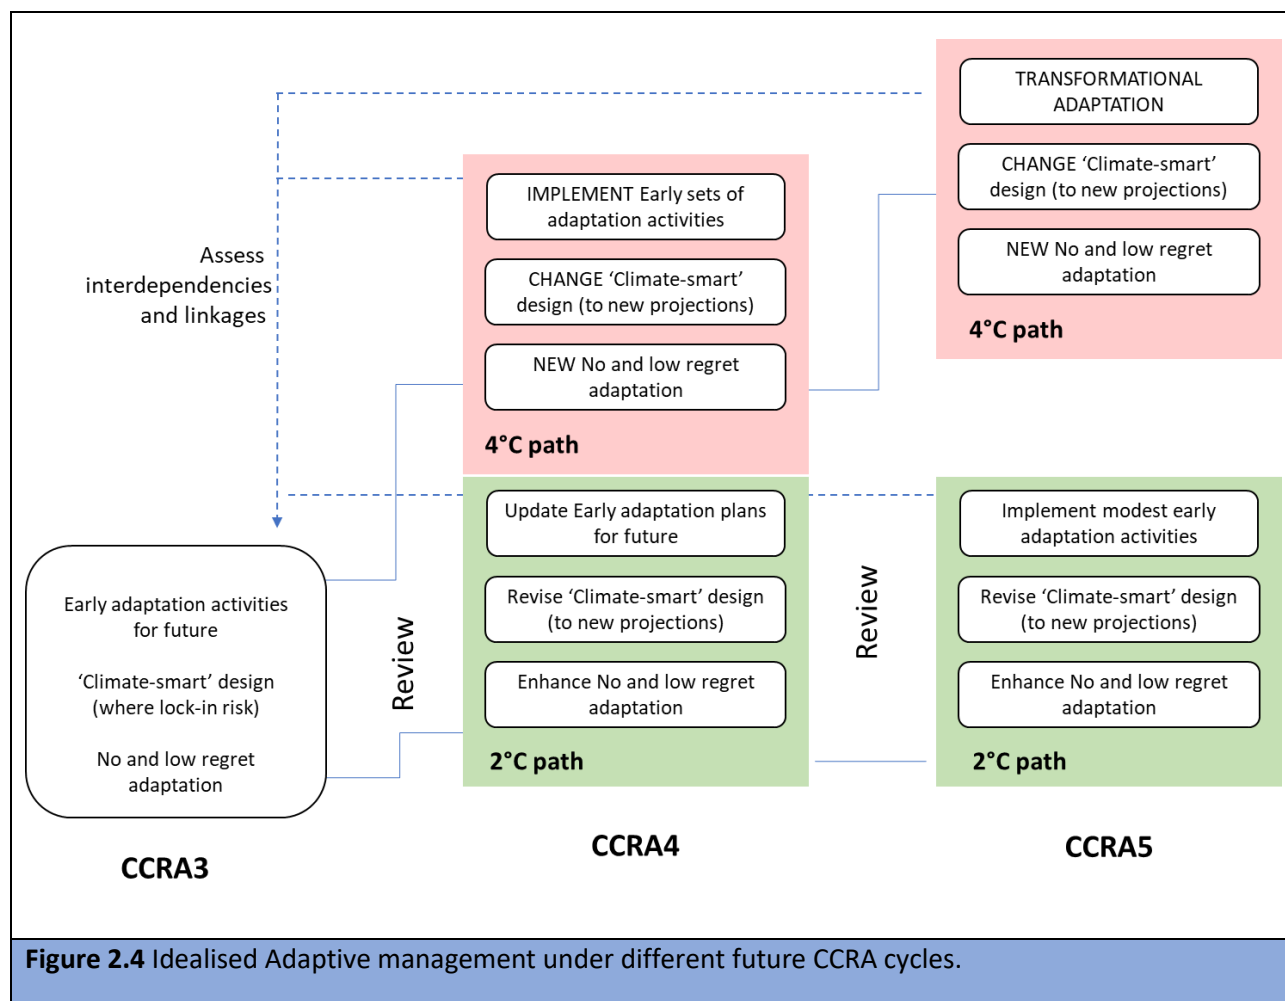

CCRA3 therefore includes more emphasis on iterative adaptive management. The aim is to encourage more consideration of risks and opportunities – and adaptation - over time and across scenarios (including uncertainty). This is particularly important because of the regular repeat cycle of the CCRA process every five years, and thus the opportunity to learn and update over time.

In the national context, this could extend to adaptation roadmaps, i.e. generic adaptation pathways. These are not to be confused with detailed dynamic adaptation route-maps, which are a decision support method used primarily at the project level (e.g. as in Thames Estuary 2100, see Reeder and Ranger, 2013), which are often called dynamic adaptation pathways (see Box 2.1).

However, while an adaptive management process is inherent in the CCRA and NAP process due to the five-year repeat cycle, operationalising this in practice is very challenging at the national scale. There are some examples, notably in the Netherlands with the Delta Committee and plans (Marcel et al., 2011) but these tend to focus on sea-level rise, which lends itself more easily to such analysis. Following the CCRA1, Defra funded an Economics of Climate Resilience study (Frontier Economics et al., 2013; HMG, 2013) which developed national level adaptation roadmaps. While this approach was informative, and identified actions over time (for successive CCRA cycles), it was found to be difficult to implement the findings at the sectoral level, because there are multiple risks (and opportunities). This indicates adaptive management (roadmaps) is more applicable at the level of individual risks or opportunities. However, developing a national adaptation roadmap for every CCRA3 risk and opportunity would be a major undertaking and has not been possible given the resources available and synthesis nature of CCRA3. Nonetheless, recent national level analysis (for the CCC) did develop indicative analysis for ten specific risks and opportunities (Watkiss et al., 2019) and found it was possible to identify lock-in and thresholds, and to include some general suggestions on moving to an adaptive management approach. CCRA3 authors were therefore asked to try and incorporate a similar discussion in Step 3 of the CCRA method, i.e. to try and consider some of the implications of lock-in and thresholds, as well as to include adaptive management suggestions for further action.

Looking forward, it would be useful to maximize the linkages between successive CCRAs (see Figure 2.4) to try and encourage a more formal iterative approach into national risk assessment. As a first step towards such an approach, CCRA3 included an additional question for authors to address in the analysis on ‘what evidence or learning would help to inform CCRA4?’

This recognises that the CCRA4, which is due for completion in 2027, will inform the fourth NAP and DA adaptation programmes for the period 2028-2032. By this time, the UK’s climate is projected to be significantly different as compared to the last century, and could be entering a period of very major climate change in the decade that follows, especially if global international mitigation efforts are below the levels needed to deliver the Paris Agreement. Therefore, authors were asked to consider what additional information might be useful to help inform CCRA4 and NAP4 decisions and they were also asked to explicitly consider where transformational adaptation might be needed.

## 2.4. CCRA3 Process

### 2.4.1 Overview of the CCRA3 Process

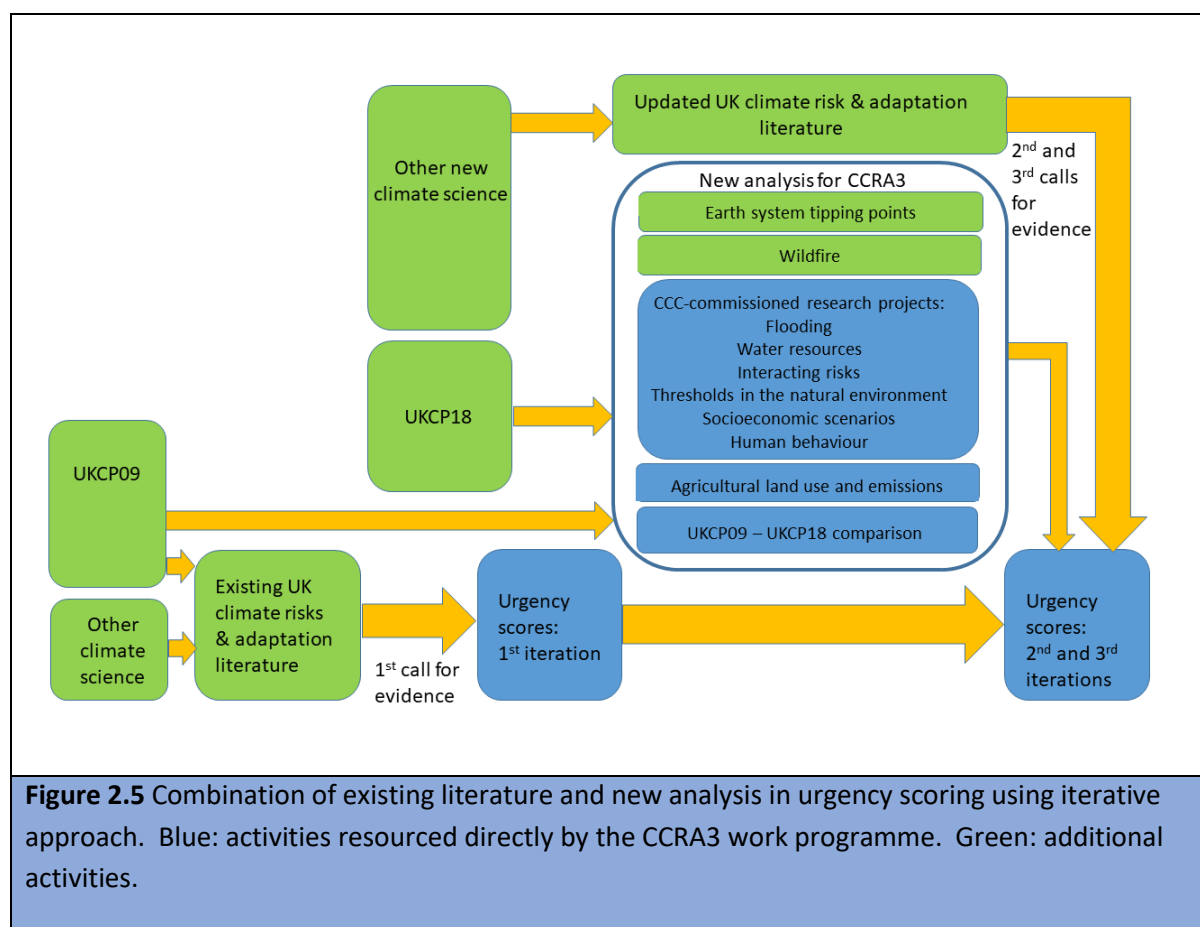

This section sets out the process involved in the development of the CCRA3 method. Building on the CCC method statement, as well as the early review work (on other national risk assessments and the academic literature), a first draft of the CCRA3 Technical Report Methodology Paper was produced in April 2019. This was reviewed internally by the CCRA3 Technical Report team and by the CCC secretariat. Following updates, a second draft of the method paper was produced and was shared with the Chapter teams for discussion, and a methodology workshop was held with this group in May 2019. The resulting changes and updates were used to produce a third version, which was reviewed by an external Expert Advisory Panel (EAP, in June 2019) and presented to the CCRA3 Project Board for comment (July 2019). The comments received were used to produce an updated version of the methodology, which went out for detailed external peer review during August and September 2019. This included review by the Government, the EAP and the external peer review panels. A large number of comments were received from this review, and these were used to produce a fifth version of the methodology chapter (along with a logged response to all 350 comments).

This version was used by Chapter teams for the first round of the CCRA Evidence analysis and urgency scoring. The methodology was operationalised through the development of a CCRA3 Risk/Opportunity template, which set out the questions that chapter teams should address (and record) for each of the three urgency method steps, along with worked examples. The template is attached in Annex 1. To support this process, a slide presentation pack on ‘how to’ implement the method was produced.

During the autumn of 2019, a number of activities (method authors or working groups) further developed the methodology. This included consideration of socio-economic scenarios including the UK Net Zero target, adaptation pathways, interacting and cross-cutting risks and equity/distributional impacts. A revised methodology chapter was produced in January 2020, along with an updated template, and discussed at a CCRA3 meeting with the chapter teams in February 2020. This was finalised for the second round of CCRA Evidence analysis in March 2020, and was also sent out for a final peer review in May 2020 by the Government, the EAP and the external peer review panel. The comments from this review were used to produce a draft final version of the methodology chapter in October 2020, which was circulated with other chapters for a final round of peer review in November 2020, but with instructions for comments to focus on updates only.

## 2.4.2 Overview of the CCRA3 Evidence Process

The CCRA3 method was applied using a three-round approach to derive the magnitude and urgency scores. This iterative process is set out in Figure 2.5.

The initial pass of the urgency scores was undertaken during late 2019, based on existing literature. A second iteration of the urgency scores was made in early 2020, following the evidence from the UKCP09-UKCP18 comparison, the outputs of CCRA3 research projects, the outputs of CCRA3-focussed research in other programmes, and new literature published later in the CCRA3 analysis and writing period. A final iteration was made in late 2020 to ensure an up-to-date assessment reflecting the latest literature.

## 2.5. CCRA3 Method Overview

The final methodology is summarised in Figure 2.6, showing the **three urgency steps** (in red) and associated questions, along with the **tasks** (in blue) that are undertaken at each of these steps. This is presented as a flow chart, which shows how the evidence at each stage progresses through towards the analysis of urgency. The key outcomes are shown in green, and include the magnitude scores (Step 1) and the urgency scores (Step 3).

The method is designed to treat evidence consistently, irrespective of the sector or system affected, creating a balanced assessment representative of the available literature. The three steps are briefly described below and then outlined in detail in the subsequent sections.

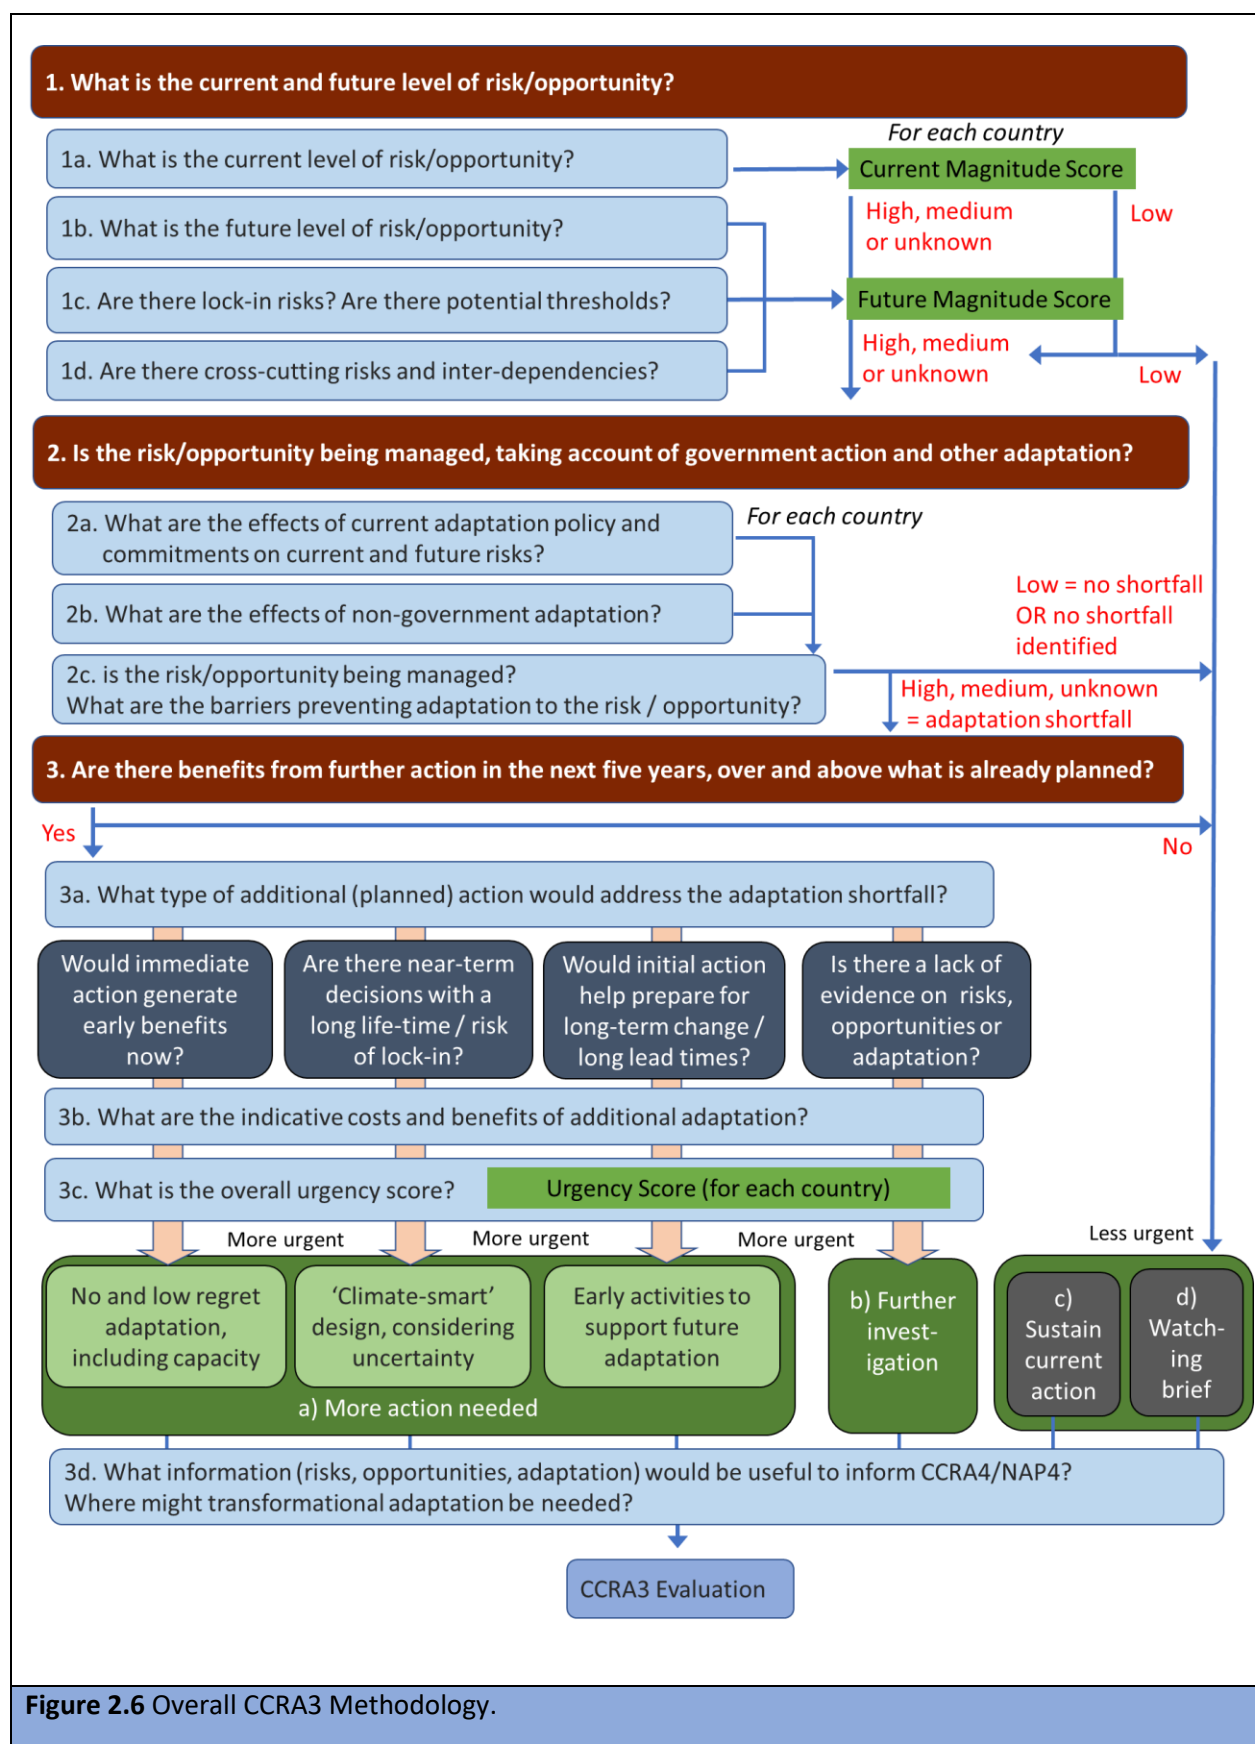

Figure 2.6 Overall CCRA3 Methodology.

### 2.5.1 Step 1: Assessment of risks and opportunities

This step undertakes the analysis of current and potential risks and opportunities, and undertakes an initial scoring of their magnitude. It is stressed this scoring is undertaken at the national level, i.e. individually for all four countries. This first step includes the following tasks:

**Step 1a. Current risks and opportunities.** This task sets out to understand and assess present-day current climate-related risks and opportunities, with a quantitative or qualitative assessment of their magnitude (see magnitude scoring Tables 2.2 and 2.3). For risks, it assesses how vulnerability, exposure and hazards affect current risks, including the influence of socio-economic drivers. For opportunities, as the IPCC hazard-exposure-vulnerability framework does not apply, the focus is on understanding the current influence of climate. This task also considers the distributional effects and potential inequalities associated with risks and opportunities. An analysis of the magnitude for risks and opportunities is made (individually) for each of the four countries (England, Northern Ireland, Scotland and Wales) (see Table 2.2 and 2.3, below), along with an analysis of the confidence in this score, based on the quality of the evidence and the level of agreement in the evidence between studies and authors (see Tables 2.4 and 2.5).

**Step 1b. Future risks and opportunities.** This task extends the analysis above to understand and assess how climate and socio-economic change may alter risks and opportunities in the future. This assesses the magnitude of future risks and opportunities for two time periods, associated with the mid-century (2050s) and late-century (2080s), and for two scenarios, broadly consistent with 2°C and 4°C warming by the end of the century (globally, relative to pre-industrial – see Chapter 1: Slingo, 2021). It also considers ranges of uncertainty, where relevant information is available. The analysis considers the changes from extreme events and variability, as well as average (slow-onset) change. The relative importance of climate change as compared with other drivers of risk (i.e. socio-economics) is reported where possible, as well as distributional effects and potential inequalities. At the end of this task, the magnitude of future climate risks or opportunities is assessed using the categories set out in Table 2.2, in the absence of planned adaptation (the ‘no additional adaptation’ scenario), for each of the four countries. It also assesses the quality of the evidence and level of agreement, i.e. confidence (see Tables 2.4 and 2.5). This task also considers the evidence on low-likelihood, high impact scenarios, which are reported but not used to assess the likely magnitude, as well as the potential linkages with Net Zero from the risk/opportunity.

**Step 1c. Lock-in and thresholds.** This task identifies the potential risks of lock-in, i.e. where decisions (or inaction) in the next five years or so could ‘lock-in’ exposure or vulnerability to future climate risks that are difficult or very costly to address later. The risk of lock-in is identified and reported in Step 1 and then used during the consideration of the benefits of further adaptation in Step 3. This task also considers possible thresholds associated with risks or opportunities, and if the exceedance of these might necessitate different adaptation interventions (for either the 2°C or 4°C warming pathways by end of century globally, and also across uncertainty ranges for each of these scenarios). The potential for lock-in and threshold risks is reported alongside the magnitude scoring table, and in the adaptation and the urgency analysis. It is noted that lock-in and thresholds can also be relevant for opportunities.

**Step 1d. Interacting and cross-cutting risks.** This task investigates cross-cutting risk linkages and interdependencies for each risk and opportunity. The analysis of interdependences is considered in

the magnitude scoring and has the potential to increase the score. For opportunities, the potential for interdependent and cross-cutting effects, as well as co-benefits or trade-offs, are also considered.

## 2.5.2 Step 2: Analysis of Government and non-Government adaptation action

This step assesses the influence of adaptation in reducing current and future climate change risks, or enhancing potential opportunities, and therefore if risks and opportunities are being managed. This second step includes the following tasks:

**Step 2a. Analysis of current adaptation policies.** This step assesses the potential benefits of current and announced adaptation policy in reducing risks or enhancing opportunities. It starts by identifying the policy landscape, identifying organisational responsibilities, and existing adaptation policy and plans from Government and other agencies. This is used to produce a current adaptation policy scenario. The analysis assesses the potential impact of existing adaptation (in place) in reducing total current risks or enhancing opportunities. It then assesses the potential impact of current and announced planned adaptation in reducing future risks or enhancing opportunities, for the same time periods as step 1b (medium-term and long-term) for different future scenarios (2°C and 4°C future warming by 2100 globally) taking account of uncertainty. This analysis is undertaken for each country as well as overall UK actions for non-devolved issues. This also assesses the quality of the evidence associated with adaptation (see Tables 2.4 and 2.5).

**Step 2b. Non-Governmental adaptation.** In cases where there are still medium or high magnitude risks in any of the likely climate/socioeconomic scenarios considered (not the low likelihood, high impact scenario), or further opportunities, the analysis considers the potential impact of other forms of adaptation. This includes spontaneous and reactive adaptation (e.g. in natural systems, from acclimatisation, or in markets) in response to the changing climate, but also planned adaptation by non-government actors, e.g. proactive, planned private adaptation. The aim is to establish whether risks will be managed in the absence of further government intervention. The analysis also considers if this adaptation is likely to be beneficial, defined through the lens of overall social welfare. For opportunities, the analysis considers whether non-governmental adaptation is likely to lead to benefits being fully realised without planned Government action, or whether additional action may be needed, including creating the enabling environment for this to happen.

**Step 2c. Analysis of Adaptation Gap and Barriers to adaptation.** At the end of this task, there is a re-analysis of the magnitude of future risks or opportunities, taking into account planned and non-governmental adaptation. This identifies if these risks/opportunities are being managed or if there is still an adaptation gap (an adaptation deficit, see section 2.7 for criteria). This analysis is undertaken for each of the four countries. Where an adaptation gap exists, the analysis considers the barriers or constraints to adaptation, i.e. what might be stopping government, private sector, households, etc. from adapting.

## 2.5.3 Step 3: Analysis of the need and urgency for additional adaptation

In the case where an adaptation shortfall is identified in Step 2 (i.e. the risk has a residual high, medium or unknown magnitude score in any of the likely climate/socioeconomic scenarios

considered), the final step considers the potential benefits of additional adaptation, over and above what is currently happening or planned. This includes the following tasks:

**Step 3a. Identify and assess possible additional adaptation action.** This identifies an additional adaptation scenario to consider further adaptation to reduce risks or enhance opportunities. It considers the type of adaptation that could be taken (aligned to Figure 2.3), whether individual areas or as a portfolio or pathway. The aim is to identify where further action would be beneficial in managing risks or opportunities, whether through direct Government intervention or by creating the enabling environment for others, but it does not identify or suggest specific adaptation policies. While the focus is on the additional action in the next adaptation reporting period, this task also considers what action might be needed now in the context of longer-term pathways. For opportunities, the task considers what additional planned adaptation might be beneficial to fully realise potential benefits from climate change.

**Step 3b. Assess the indicative costs and benefits of additional action.** This task assesses the economic rationale for, and the indicative costs and benefits of the identified further action (including wider co-benefits or trade-offs), primarily in qualitative terms. This information helps to identify the possible areas for action (aligned to Figure 2.3) and to provide some context on the possible benefits of further action as compared to costs. This task also checks if there are any synergies or trade-offs with mitigation.

**Step 3c. Analysis of overall urgency scores.** At the end of this step, an analysis is made of the overall urgency score of each risk or opportunity. This categorises risks and opportunities into one of four scores: 'more action needed'; 'further investigation'; 'sustain current action' or 'watching brief'. Alongside this ranking, the assessment describes what type of action might be beneficial to manage the risks or opportunities, particularly in the context of the next National Adaptation Programme and adaptation programmes of the DAs. The urgency scores are set out in each chapter and summarised in the Advice Report. This step also assesses the quality of the evidence for the urgency ranking (see Tables 2.4 and 2.5).

**3d. Learning and Evaluation.** The last step is to move beyond the five-year focus of the CCRA3 cycle and ask the question of where additional information or analysis would be useful to inform CCRA4 and subsequent adaptation programmes, i.e. with respect to risks and adaptation. Teams were also asked to explicitly consider if/where transformational adaptation might be needed.

Finally, following the publication of the CCRA3 Evidence and Government Report and the next set of national adaptation programmes, it is recommended that a formal evaluation of CCRA3 should be undertaken prior to the CCRA4. This would need to be undertaken in 2023, after the publication of the CCRA3 Technical Report, Advice Report, Government Report and the National Adaptation Programme. As yet, resource has not been allocated to this task and will need to come from the UK Government.

## 2.6 Detailed Description of the Method

The detailed methodology for CCRA3 Technical Report is set out below by task and step.

## 2.6.1 Step 1. Assessment of Current and Future Risks and Opportunities

The first step in the overall method is the assessment of risks and opportunities (see Figure 2.7). This step starts with the analysis of current and potential risks and opportunities, and undertakes an initial scoring of their magnitude, then considers how these may change in the future.

**Figure 2.7** First step in the overall method and urgency analysis.

These steps are described in more detailed below.

### 2.6.1.1 Task 1a. Understand Present Day Risks and Opportunities

The purpose of the first task is to provide a summary of the current risks and opportunities from climate and non-climate stressors. An understanding of how hazard, exposure and vulnerability to the current climate (including climate change that has already taken place) allows for a better understanding of how risks and opportunities may change in the future. It also provides inputs to help assess the size of the current adaptation deficit.

The key terms for defining risks in CCRA3 (see Box 2.1) are based **on the IPCC definition of risk, and the components of hazard, exposure and vulnerability** (IPCC core concepts, IPCC, 2014a: IPCC, 2014b). This is worth being clear about as definitions of ‘risk’ – and methodological approaches - do vary across UK government (see Introduction Chapter: Betts and Brown, 2021). To assess current climate-related risks, CCRA3 authors were asked to assess the following:

- The current risks of climate on economic, social and environmental systems. This includes the consideration of year-to-year variability and extreme events, as well as from average climate.
- The key socio-economic factors that influence vulnerability, how these interact with climate and what is their relative importance or contribution. To support this task, an additional CCC research project was commissioned to update UK socio-economic data to use in the other research projects and across the report.
- Given the above, what the magnitude of the risks and opportunities is at present. This uses the magnitude table shown in Table 2.2. This scoring was undertaken separately for each UK country (England, Northern Ireland, Scotland and Wales), including the adjustment factors in Table 2.3.
- Assesses the quality of the evidence and level of agreement, i.e. confidence (see Tables 2.4 and 2.5)

A key focus for authors was to identify and document additional changes in the current risk or opportunity observed since CCRA1 or CCRA2. This included any weather-related thresholds, geographic ‘hotspots’ or types of event that pose a specific risk.

It is noted that the climate of the UK has already changed since pre-industrial times, and significant changes have occurred since the 1961-1990 period in both mean climate and extremes (Kendon et al., 2018), as outlined in Chapter 1 (Slingo, 2021). These changes become more important with each successive CCRA. This includes evidence of warming in annual mean temperature, the hottest and coldest days of the year, changes in annual precipitation, the most intense rainfall events, and the length of warm spells, dry spells and growing season length.

An additional element that was included in CCRA3 is the evidence that even in the present day, there is a higher probability of climate events that could happen but have not yet occurred in the observational records (Thompson et al., 2017 and Smith et al., 2019), as an example, temperatures exceeding 40°C. This has been considered using new methods that consider the likelihood of extreme and unprecedented weather events under the current climate, using a technique known as “UNSEEN” (UNprecedented Simulation of Extremes with ENsembles), as outlined in Chapter 1 (Slingo, 2021). Information on these events were compiled, and chapter authors were encouraged to consider the implications of these results, i.e. whether they affect their assessments of present-day climate impacts and risk. Additional information is given in Box 2.4 in the next section below.

For opportunities, the focus was also on understanding the current influence of climate on economic, social and environmental systems. However, the IPCC hazard-exposure-vulnerability framework does not work well for opportunities. Instead, the focus was on the magnitude of potential beneficial consequences (using the same categories of magnitude as for risks, but opposite in sign). This can involve the positive existing influence of the climate (i.e. as a baseline to allow comparison of rising future benefits under climate change) or the current negative impact of extremes to allow analysis of future decreases from climate change, such as for cold-related extremes.

At the end of this task, an analysis of the magnitude of current risks or opportunities was made (see section and Table 2.2 below). It is stressed that this magnitude score is undertaken for each individual country (England, Northern Ireland, Scotland and Wales), see also Table 2.3. The assessment also considers the confidence of the risks or opportunity, based on the level of agreement combined with the quality of the evidence used.

An interesting finding from the application of this approach is that adaptation is influencing current risks and opportunities. This creates new methodological challenges. In cases where the analysis of current risks (or opportunities) is based on observed information, these will reflect current levels of adaptation. However, any observed changes will also be influenced by other drivers, e.g. from changes in exposure or vulnerability, plus non-climate policy. This makes it extremely difficult to attribute the benefits of current adaptation in reducing current risks (without more detailed counterfactual analysis). Furthermore, to analyse the benefit of current adaptation, it is necessary to go through the tasks in Step 2 (identify who is responsible, what current adaptation policy is, and how effective it is). For these reasons, the analysis of the role of current and future adaptation was included in Step 2.

More information on the magnitude and confidence scoring, and supplementary activities on economic valuation and distributional effects and inequalities, is given below.

#### 2.6.1.1.1 Magnitude scoring

The final task in the first step of the method is to assign a magnitude score to each risk and opportunity. This is undertaken for both current and future time periods.

Most risk assessments seek to assign an overall magnitude using a combination of likelihood and impact. For example, the UK National Security Risk Assessment and the National Risk Register (NRR) (HMG, 2020) - which consider risks (national-scale emergencies) assuming a reasonable worst case - assesses the combination of likelihood (within the next five years) and the impact severity to provide an overall ranking of risks. CCRA3, however, is working with a broader defined set of risks (see Box 2.1 key terms), which include long-term trends as well as probabilistic events, over a much longer-time frame.

A magnitude scoring approach was developed in CCRA2 to capture potential impact of trends and probabilistic events, and this has been applied again in CCRA3. The impact levels were set based on a review of the NRA.

This magnitude table has been updated in CCRA3. This extended the table with a larger number of categories, particularly to capture potential magnitude for the natural environment and natural capital, see Box 2.3 below (as these are not captured in many existing risk frameworks, such as the NRR). The new table added additional categories (rows), but also undertook a re-analysis to improve the cross comparability between magnitude rankings (columns) and between categories (rows) using a valuation and benchmarking exercise. This resulted in some changes in the magnitude descriptions as compared to CCRA2. The updated categories and magnitude scores used in CCRA3 are shown in Table 2.2.

Where possible, the evidence was matched to the relevant category and magnitude in the table. However, in some cases such evidence does not exist, and the analysis allows for expert judgement to be used. To make this process robust, this was based on the consensus (through consultation and discussion) of Technical Report authors, the CCC, and the CCRA peer reviewers.

A further change in CCRA3 has been to provide different magnitude tables for each UK country (England, Northern Ireland, Scotland and Wales). This aims to provide an equivalent relative magnitude score of risks or opportunities for each country, i.e. to provide consistent relative scores of what is important for each DA. This approach was used because the use of a single scoring table led to important omissions (of magnitude) for the three DAs. This does, however, mean that risks or opportunities in each country do not have the same absolute risk or opportunity level. For England and the UK, Table 2.2 was used without adjustment. For other DAs, the values were adjusted using the information in Table 2.3. Note that scoring below the level of the DAs (at a more disaggregated level or for hotspots) has not been undertaken.

The evidence from the review was used with Table 2.2 and 2.3 to assign a low, medium or high magnitude to each risk or opportunity - there is also an option of an 'unknown' score in case there is insufficient evidence. Opportunities were assessed using the same magnitude level, but with opposite sign.

It is stressed that these categories are not mutually exclusive, but are a set of options from which chapter authors could choose based on the evidence available. They were asked to choose from the categories to score a risk in the fullest way possible with the evidence available. It is acknowledged that in some cases, the available evidence will represent an underestimate of the total scale of risk or opportunity, thus a logarithmic scale is used to reduce the sensitivity to gaps in the evidence.

The other main development in CCRA was the consideration of future risks across different future time periods and scenarios, in line with the customer request. The resulting scoring table is presented in section 2.6.2.

**Box 2.3 Natural Environment and Natural Capital.**

In considering the size of risks or opportunities in the natural environment, different types of quantification are possible depending on what is being measured. This could be the size of a natural capital asset (see below), the size of an area containing different assets, the change in the quality or quantity of a natural asset, the services it provides to people, or the value of those services. CCRA2 only provided magnitude categories for the area or size of habitats and species affected, but when looking at the definition of natural capital, it is clear that these measures do not capture the total risk. The additional categories in Table 2.2 are intended to allow for a fuller analysis depending on the evidence available. While the terms natural environment and natural capital are both included here to ensure comparability between this and past CCRA2s, going forward (including in CCRA4), it would be useful for these terms to be consolidated.

Natural capital is defined by NCC (2017) as follows: Natural capital are the elements of nature that directly or indirectly produce value to people, including ecosystems, species, freshwater, land, minerals, the air and oceans, as well as natural processes and functions. Natural capital is a broad term that includes many different components of the living and non-living natural environment, as well as the processes and functions that link these components and sustain life. Natural capital assets include all biotic and abiotic assets (e.g. species, ecological communities, soils, freshwaters, land, atmosphere, minerals, sub-soil assets and oceans) and include both designated and undesignated habitats and species. The magnitude of a risk on a natural capital asset can be measured using any of the quantitative or qualitative indicators in Table 2.2, and not just those described using the term 'natural capital'.

**Table 2.2** CCRA magnitude categories for UK and England.

	<b>High Magnitude</b>	<b>Medium Magnitude</b>	<b>Low Magnitude</b>
Quantitative evidence	<i>Major annual damage and disruption or foregone opportunities:<sup>1</sup></i>	<i>Moderate annual damage and disruption or foregone opportunities:</i>	<i>Minor annual damage and disruption or foregone opportunities:</i>
	-£hundreds of millions damage (economic) or foregone opportunities, and/or	-£tens of millions damage (economic) or foregone opportunities, and/or	-Less than £10 million damage (economic) or foregone opportunities, and/or
	-Hundreds of deaths <sup>2</sup> , thousands of major health impacts, hundreds of thousands of people affected / minor health impacts, and/or	-Tens of deaths, hundreds of major health impacts, tens of thousands of people affected / minor health impacts. and/or	-A few deaths, tens of major health impacts, thousands of people affected / minor health impacts, and/or
	-Tens of thousands of hectares land lost or severely damaged <sup>3</sup> , and/or thousands of km of river water/km <sup>2</sup> of water bodies affected, and/or	-Thousands of hectares of land lost or severely damaged, and/or hundreds of km of river water/km <sup>2</sup> of water bodies affected, and/or	-Hundreds of hectares of land lost or severely damaged, and/or tens of km of river water/km <sup>2</sup> of water bodies affected, and/or
	-Major impact (~10% or more at national level) to valued habitat or landscape types (e.g. BAP habitats, SSSIs), and/or	-Intermediate impact (~5% at national level) to valued habitat or landscape types (e.g. BAP habitats, SSSIs), and/or	-Minor impact (~1% at national level) to valued habitat or landscape types (e.g. BAP habitats, SSSIs), and/or
	-Major impacts on or loss of species groups, and/or	-Intermediate impacts on or loss of species groups, and/or	-Minor impacts on or loss of species groups, and/or
	-Major impact (10% or more at national level) to an individual natural capital asset and associated goods and services <sup>4</sup> , and/or	- Intermediate impact (1 to 10% at national level) to an individual natural capital asset and associated goods and services, and/or	- Minor impact (~1% or less at national level) to an individual natural capital asset and associated goods and services, and/or
	-Major loss or irreversible damage to single nationally iconic heritage asset (e.g. Stonehenge, Giants' Causeway)	-Medium loss or irreversible damage of nationally iconic heritage asset (e.g. Stonehenge, Giant's Causeway)	-Low loss or irreversible damage to nationally iconic heritage asset (e.g. Stonehenge, Giants' Causeway)
Qualitative evidence	Expert judgement of chapter authors, confirmed with agreement across authors, CCC and peer reviewers suggest there is a possibility of impacts of the magnitude suggested above.		

<sup>1</sup>This could be an annual average or expected annual damages. Where evidence is only related to a single event, authors should make a judgement on the magnitude and state this in their assumptions.

<sup>2</sup>The implied value of number of deaths is broadly in line with the value of prevented fatalities used by Government in the appraisal of policies (see DfT, 2019). It should be noted that this applies to an 'average' prevented fatality, i.e. someone of average age and who is otherwise healthy. The number of major injuries / major health outcomes, and minor injuries / minor health outcomes / people affected, are also in line with values used in appraisal.

<sup>3</sup>These values are based on the average value for an agricultural hectare of land in England that is estimated to be £22k ([https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment\\_data/file/710539/Land\\_Values\\_2017.pdf](https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/710539/Land_Values_2017.pdf)) It is noted that the average value for residential, commercial and industrial land is much higher, and thus if urban land areas are affected, these scoring categories might be adjusted, i.e. so that a lower number of hectares would be equivalent to a low, medium or high ranking.

<sup>4</sup>The areas of natural capital assets are based on the definitions and reported values in the ONS Natural Capital Accounts and expert analysis of equivalence, <https://www.ons.gov.uk/economy/environmentalaccounts/bulletins/uknaturalcapitalaccounts/2019>.

## 2.6.1.1.2. Quality of Evidence and Level of Agreement (Confidence)

In the IPCC AR5 synthesis process (Mach et al., 2017), assessment findings are evaluated against (a) evidence and agreement, (b) confidence, and (c) likelihood. For CCRA3, a formal method was used to assess the quality of the evidence used in terms of evidence and agreement, and thus confidence.

In terms of the quality of evidence, there is a requirement that evidence be from:

- Published papers in academic and professional journals;
- Papers *in press* in academic and professional journals (*copies of these should be made available to the reviewers, and have been published by the time the CCRA3 Technical Report is published*);
- Published (or publicly available, including at cost) reports from research institutions, Government agencies, Government committee reports, papers and minutes (and responses to consultations), third-sector organisations or private sector companies (including contract research reports), as well as grey literature that has been through a review process and is published.

These sources of evidence were recommended *not* to be used:

- Papers that have been ‘submitted’ or are ‘in preparation’ at the time of the publication of the CCRA3 Technical Report:
- Reports that are not publicly available, even at cost.

To assess the confidence a simplified version of the IPCC AR5 approach is used, looking at the combination of the quality of evidence as set out above (from high to low), along with the level of agreement between studies and experts (high to low). These are combined to give the overall confidence ranking. Note that the confidence is a measure of the strength of evidence and

agreement, and is different to the likelihood that the risk or opportunity will occur. Table 2.4 provides the criteria used to assign a confidence score to each risk and opportunity in Step 1. There is also a similar quality of evidence and agreement included for assessing the effect of adaptation in Step 2 and if additional action would be beneficial in Step 3. Additional supplementary information for assessing the quality of evidence is included in Table 2.5.

**Table 2.3** Quality of Evidence and Level of Agreement (Confidence) – Criteria.

	<b>High</b>	<b>Medium</b>	<b>Low</b>
<b>Step 1: Assessment of current and future risk</b>	Multiple sources of independent evidence based on reliable analysis and methods, with widespread agreement between studies and experts.	Several sources of high-quality independent evidence, with some degree of agreement between studies, and/or widespread agreement between experts.	Varying amounts and/or quality of evidence and/or little agreement between experts, or assessment is made using only expert judgement.
<b>Step 2: Assessment of the effect of planned and non- Governmental adaptation</b>	High quality evidence of the effects of future adaptation in managing the risk and high agreement between experts.	Some evidence on the effects of future adaptation in managing the risk and/or high agreement between experts.	Little/no/contrasting evidence of the effects of future adaptation in managing the risk and little agreement between experts, or assessment is made using only expert judgement.
<b>Step 3: Assessment if additional action would be beneficial</b>	High quality evidence of benefits of future adaptation on risk and high agreement between experts.	Some evidence on benefits of future adaptation and/or high agreement between experts.	Little evidence of the benefits of future adaptation and little agreement between experts, or assessment is made using only expert judgement.

**Table 2.4** Supplementary information for assessing Quality of Evidence.

High quality evidence	Some evidence	Little evidence
<ul style="list-style-type: none"> <li>Multiple sources of evidence that contain similar results</li> <li>Evidence of validation using different datasets</li> <li>Based on robust techniques</li> <li>Data used is of a high quality</li> <li>Evidence has been peer reviewed</li> <li>Remains relevant</li> <li>Use of relevant indigenous and local knowledge</li> </ul>	<ul style="list-style-type: none"> <li>Some elements of “high quality evidence” and “little evidence”</li> </ul>	<ul style="list-style-type: none"> <li>No, or very few, sources of evidence</li> <li>Based on only one dataset</li> <li>Based on weak methodologies (e.g. anecdotal evidence)</li> <li>Poor quality data</li> <li>Evidence has not been peer reviewed</li> <li>No longer relevant</li> <li>No use of relevant indigenous and local knowledge</li> </ul>

## 2.6.2 Task 1b Assess Future Risks and Opportunities

The second task undertakes an analysis of the future risks and opportunities of climate change, repeating the steps above but for future time periods. This step also considers risks in terms of hazard, vulnerability and exposure. However, it involves the additional challenge of different future climate projections, uncertainty and future socio-economic change. The task applied the IPCC Core Concepts to assess future risks, while noting that the components of hazard, exposure and vulnerability are dynamic and change over time. For opportunities, the focus was on the magnitude of potential consequences. The CCRA authors were asked to consider the following issues:

- How relevant climatic factors, and risks or opportunities, may change in the future, including an assessment of the uncertainties.
- How socio-economic factors could influence the risk/opportunity in the future and their influence on magnitude.
- To record evidence for the risks and opportunities in the mid-century (2050s, i.e. 2041-2060) and late-century (2080s, 2070 – 2099), including the uncertainties associated with the climate evidence. This also included the differences in future risks or opportunities for pathways to warming of 2°C and 4°C by the end of the century, globally, relative to pre-industrial, where available, including quantification of uncertainty. Authors were asked to record the reference period used (noting UKCP18 is now using 1981-2000). They were also asked to document the assumptions on socio-economic scenarios and to document the relative importance of climate versus socio-economic (if available). When evidence was based on global warming levels, the teams were asked to document the Global Warming Level (GWL) and time period (e.g. 2°C GWL global mean temperature (GMT), relative to preindustrial, exceeded in time period centred on 2070).
- To capture and report on any low-likelihood high-impact extremes or scenarios. This included High++ runs, tail-end risks, higher warming scenarios (e.g. > 4°C by 2100) and earth system tipping points.
- To identify any potential risks of lock-in (see section 2.3), or loss of opportunities, particularly where decisions might be taken in the next reporting period (the next 5 years). They were also

asked to document important thresholds (whether biophysical thresholds, engineering, performance or policy thresholds, see section 2.3) and consider if the exceedance of these varied over scenarios or across projections (including uncertainty). Authors were also asked to assess the potential synergies and trade-offs with Net Zero, as part of a separate set of questions.

- To assess the magnitude of the risks and opportunities in the future and how important climate change is in the realisation of a risk.

At the end of this task, the same magnitude scoring approach as for Task 1a (Tables 2.2 and 2.3) were used to score future risks and opportunities. This was undertaken separately for each UK country (England, Northern Ireland, Scotland and Wales).

For the first round of magnitude scoring (in early 2020), authors were asked to assess future magnitude (High, Medium, Low or Unknown) as one single score, which reflected the highest score across different time periods, scenarios or pathways, and across the uncertainty range. Note that this approach is inherently precautionary, and followed the approach used in CCRA2.

For the second round of scoring (summer to autumn 2020), authors were asked to assess magnitude in line with the request from Government. This included information on potential risks and opportunities under different time periods (mid-century and late century) and different future pathways, defined broadly in terms for 2°C and 4°C pathways by the end of the century (globally, relative to pre-industrial levels)<sup>2</sup> as well as for each DA. Authors were asked to provide the highest score across the uncertainty range in each cell. This is shown in Table 2.6 below.

An assessment of the quality of the evidence and level of agreement, i.e. confidence, was also undertaken and included in brackets after the magnitude score (Tables 2.4 and 2.5).

A number of additional aspects to consider were also requested. Authors were asked to consider the implication of different rates of climate change between the two scenarios, not just the absolute change, as this is extremely important in determining adaptation potential. They were also asked to consider the distributional effects and potential inequalities associated with risks and opportunities (see section in 2.6.1.).

---

<sup>2</sup> This did not include a scenario that limits warming to 1.5°C, i.e. to consider an additional scenario that was closer to the Paris Agreement text of pursuing efforts to limit warming to 1.5°C relative to pre-industrial. This 1.5°C scenario has received more attention following the recent IPCC Special Report on Global Warming of 1.5 °C (IPCC, 2018). CCRA3 has not considered such a 1.5°C scenario, see Chapter 1. This is primarily due to the lack of information to inform a risk assessment at this level. However, it is noted that global emissions are still rising and current pledges for reducing emissions, as set out in the Nationally Determined Contributions, indicate warming of above 3°C (UNEP, 2019; UNEP, 2020). This analysis has also identified limiting warming to 1.5°C would require global emissions to fall by 7.6% per year from 2020 to 2030. The progress towards such reductions will become clearer during the Global Stocktake (in 2020, now delayed to 2021), which will review the implementation of the Paris Agreement and assess collective progress and updates towards achieving the Paris Agreement and its long-term goals.

**Table 2.5** Magnitude Scoring summary table in CCRA3. Each cell was assigned a score of low (L), medium (M), high (H) or unknown (U).

	Present Day	2050s		2080s	
Country		On a pathway to stabilising global warming at 2°C by 2100*	On a pathway to 4°C global warming at end of century#	On a pathway to stabilising global warming at 2°C by 2100*	On a pathway to 4°C global warming at end of century#
England	L/M/H/U	L/M/H/U	L/M/H/U	L/M/H/U	L/M/H/U
Northern Ireland	L/M/H/U	L/M/H/U	L/M/H/U.	L/M/H/U	L/M/H/U
Scotland	L/M/H/U	L/M/H/U	L/M/H/U	L/M/H/U	L/M/H/U
Wales	L/M/H/U	L/M/H/U.	L/M/H/U.	L/M/H/U	L/M/H/U

\*This scenario is defined as the global mean temperature rise stabilising at 2°C ± 0.5°C by 2100. This includes pathways that align to the Paris Agreement and the goal of limiting global mean temperature rise to well below 2°C above pre-industrial levels, and also pathways that slightly exceed this global warming level, including “overshoot” pathways.

# This scenario is defined around outcomes that lead to a 4°C global mean temperature rise above pre-industrial levels at the end of the 21<sup>st</sup> century (2080 to 2100). This is considered an upper bound of global warming rates that could occur with current policies, considering various combinations of emissions scenarios and climate system feedbacks (see Introduction chapter: Betts and Brown, 2021).

A supplementary analysis was undertaken to investigate the indicative monetary impacts of future risks and opportunities (see section in 2.6.1.). Alongside this magnitude score, authors were also asked to consider possible low likelihood, high impact extremes and scenarios (including high warming outcomes that reach 4°C before 2070, High++, tail-end risks and earth system tipping points). However, the evidence (on low likelihood, high impact) was not used in the magnitude scoring.

It is stressed that the primary aim of this task was to identify the magnitude of future risk and opportunities in the absence of planned adaptation - the analysis of adaptation in managing these future risks is undertaken in step 2. However, for studies that undertake modelling of risks and adaptation, including the CCRA3 research projects, it was necessary to define no adaptation baselines. To address this, CCRA3 defined a Step 1 future ‘no additional adaptation’ scenario. This included ‘common sense’ assumptions on what might happen in the absence of planned policy. This is the same approach that was used in CCRA2.

One lesson from the application of the method for opportunities was that in most cases, these are complicated by the presence of potential risks alongside benefits, e.g. where there were potential benefits identified from a warmer average climate, there were often still potential impacts from changing variability or extremes, or other factors such as water availability limiting the ability for enhanced crop growth in warmer temperatures. In such cases, authors were asked to document both aspects.

More information on key elements of this task – on climate projections, socio-economic scenarios, the Net Zero analysis, and tail-end risks - are given below.

### 2.6.2.1 Climate change projections, including uncertainty

The starting point for the assessment of future risks and opportunities are the climate projections, set out in Chapter 1 (Slingo, 2021). There are different ways to use these projections in climate risk assessments, and to ensure consistency of reporting for different risks and opportunities. However, these consistency issues are a particular challenge for a synthesis exercise, such as CCRA3, because it must draw on various evidence that uses different projections and approaches.

In previous CCRAs, and in most impact studies, analysis or evidence is assessed for future scenarios and time periods. In CCRA1, a consistent set of projections and time slices from UKCP09 were used and applied to every risk or opportunity. This used the UKCP09 time slices<sup>3</sup> for the 2020s (represented by the mean climate for 2010-2039), 2050s (2040-2069), and 2080s (2070-2099) relative to a baseline period of 1961-1990 and considered the UKCP09 low, medium and high UKCP09 projections, as well as sampling the probabilistic projections<sup>4,5</sup>. CCRA2 was a synthesis exercise, but asked contributors to report evidence for the 2050s, and 2080s, including a discussion on the uncertainties associated with the climate evidence used. The authors considered climate projections on a country-by-country basis, for the subsequent risk and opportunity assessment. In CCRA2, this was based on country averages, but with commentary around how this varied spatially.

As set out in Chapter 1 (Slingo, 2021), and earlier in this Chapter, the UK has now published a new set of climate projections, the UK Climate Projections 2018 (UKCP18). The UKCP18 overview report (Lowe et al., 2018) reported changes for two future time periods (of twenty years) – the 2050s (2041-2060) and 2080s (2080 – 2099), relative to a baseline period of 1981-2000, though the UKCP18 projections also provide a time series that runs continually from pre-present through to 2100. The UKCP18 products allow analysis of projections with the RCP2.6, RCP4.5, RCP6.0 and RCP8.5 emissions scenarios, and also some potential to extract information specifically for 2°C and 4°C global warming levels relative to pre-industrial (Gohar et al., 2018). The latter allows for an alternative approach to reporting results, using global warming levels (GWL), rather than for time periods for emission / forcing scenarios. However, it is stressed that for adaptation, the time period when risks or opportunities occur and the rate of adaptation needed are important, and therefore approaches that use GWL need to document time, as has been done here. It is also possible to extract subsets of the projections that follow pathways that reach these global warming at specific times such as at the end of the 21<sup>st</sup> Century, and this has been done in some of the CCRA3 supporting research (Sayers et al., 2021) and in other literature drawn on for the CCRA3 assessment (e.g. Arnell et al., 2021)

---

<sup>3</sup> Note that projections are generally presented as averages for twenty-year or thirty-year time periods, not as decadal or yearly averages, because decadal periods are still subject to significant natural variability and may not give a good indication of the long-term climate.

<sup>4</sup> CCRA1 sampled across the p10, p50 and p90 for the UKCP09 low medium and high projection and focused on nine combinations (results) as follows: 2020s: p10 Medium, p50 Medium, p90 Medium; 2050s: p10 Low, p50 Low, p50 Medium, p50 High, p90 High; and 2080s: p10 Low, p50 Low, p50 Medium, p50 High, p90 High.

<sup>5</sup> It is interesting to note that the CCRA3 Independent Assessment and the next national adaptation programme period (2023-2027) is at the mid-point of the UKCP09 2020s time period.

In gathering existing information on the evidence in CCRA3, authors were asked to understand and assess how climate and socio-economic change may alter climate-related risks and opportunities for the mid-century (the 2050s, often represented by the mean climate for 2040 -2060) and late-century (2080s, or 2070 – 2100), for 2°C and 4°C warming pathways by the end of the century (globally, relative to pre-industrial levels), where possible. Authors were asked to be explicit about the reference (baseline) periods used for evidence.

As highlighted earlier, much of the literature on future UK climate risks assessed in CCRA3 is based on UKCP09. In practical terms, this raised an issue on how to use information from UKCP09 in CCRA3, given the different baseline and future periods<sup>6</sup>, as well as the updated information from UKCP18. To address this, the UK Met Office produced new information for authors, based on the key metrics of relevance for the identified risks and opportunities (see Chapter 1: Slingo, 2021). A summary is provided in Box 2.4.

In collecting this information, and assessing adaptation, it is important to consider uncertainty. This involves two issues. The first is that there are alternative future emission pathways, which is addressed by using several sets of projections sampling the emissions scenarios associated with the Representative Concentration Pathways, RCPs, as in UKCP18. The second issue is that different climate models do not all give the same results for UK climate for a given emissions scenario or even at the same global warming level. This can be considered by using different models in an ensemble, or as in UKCP18, with the derivation of a conditional probability range, with outputs of (for example) 10<sup>th</sup>, 50<sup>th</sup> and 90<sup>th</sup> percentiles. It is essential to recognise this uncertainty, not to ignore it.

#### Box 2.4. Supporting Climate Analysis for CCRA3.

**UKCP09 to UKCP18.** As noted in Chapter 1 (Slingo, 2021), some of climate risk-related quantities in UKCP18 are quite different to those in previous projections, while others are similar. Analysis by the UK Met Office for CCRA3 assessed key climate metrics (of relevance to the CCRA3 risks and opportunities) and provided information on when these differences were extensive enough to affect the advice previously provided by the CCRA around estimates of magnitude drawn from UKCP09, and also to take account of similarities when assessing confidence. To do this, the analysis in CCRA3 has used the following procedure for each Risk, (illustrated earlier in Figure 2.1).

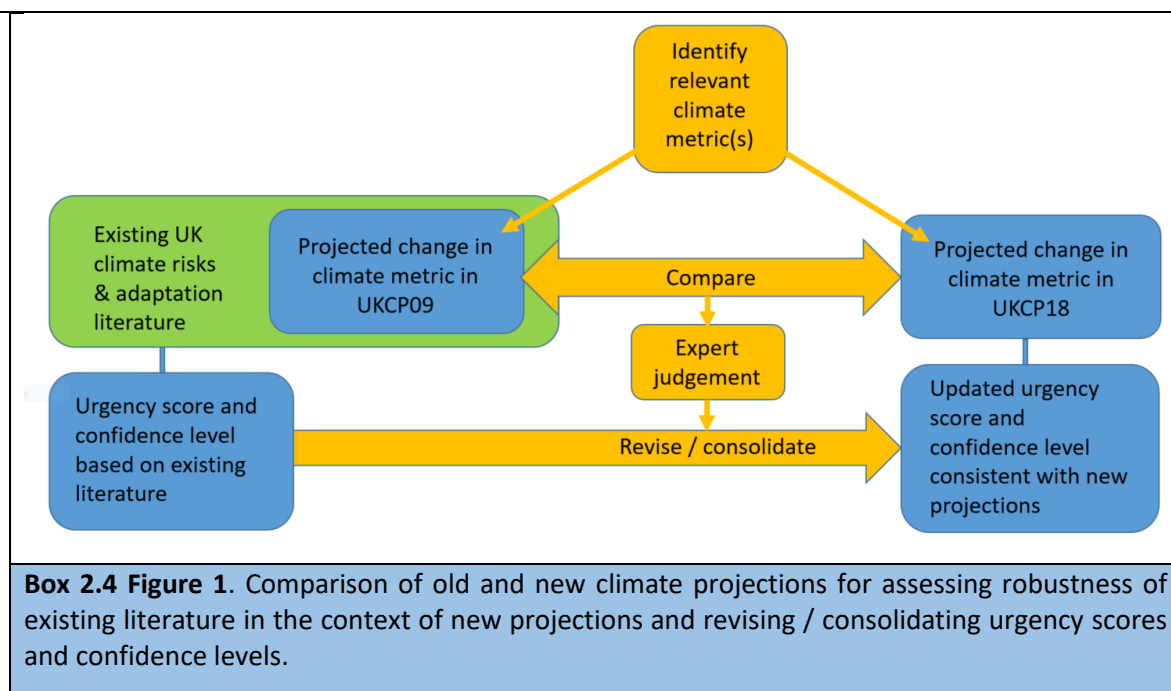

- Produce an initial magnitude score based on the existing UKCP09-based literature where relevant.
- Identify the key climate variables or metrics used to quantify the hazard component of the risk or opportunity in the existing UKCP09-based literature.
- Compare the projected changes in these variables and metrics from UKCP09 with the equivalent changes in UKCP18.
- Using expert judgement, assess whether the differences between the changes projected by UKCP18 and UKCP09 are substantial enough to justify a different magnitude score.
- If a different magnitude Score is justified by the UKCP18 projections, critically examine the underlying reasons for the difference in the projected climate variable / metric and form a

<sup>6</sup> Earlier impact studies, such as those based on UKCP09, use an earlier reference period (usually 1961-1990), but this is now out of date with respect to the current time (i.e. the year 2020). It is stressed that the magnitude does vary depending on whether risks compared with 1961-1990, 1981-2000 or the current.

judgement on which is the most robust. Reflect this change by use of an appropriate confidence statement. If a different magnitude Score is not justified, again critically examine the reasons for the similarity in the projected climate variable / metric, and assign an appropriate confidence level.

- Ascertain if the change in magnitude warrants a change in the urgency score.

The UKCP09-UKCP18 comparison used the UKCP09 regional climate model (RCM ensemble) and was performed most systematically with the UKCP18 12km projections, but the 2.2km projections were also considered. Furthermore, the UKCP18 60km global simulations were also used to provide further context. The results were examined to assess whether the changes in key metrics – and subsequent risks and opportunities where relevant - were substantial enough to justify a different magnitude and urgency score.

**Volatility, extremes and UNSEEN.** The climate of the future can be viewed as a long-term climate trend with natural variability superimposed on to it and providing volatility, which will be experienced as future weather. UKCP18 focuses more than UKCP09 on capturing climate volatility, with the conditional probability range including natural variability down to the monthly scale and the ensembles of realisations from global and regional climate models providing a tool to examine sub-monthly volatility (Lowe et al., 2018). Additionally, other tools are now available in the climate literature that focus on present day volatility and the possibility of seeing unprecedented events not captured in the relatively short observational record. These include the UNSEEN approach (Thompson et al., 2017), which uses many historical simulations to provide additional realisations of the events that might occur in the current climate. When assessing climate impacts, it is important to go beyond the long-term mean changes and to take account of volatility and extreme events, including unprecedented events. This can significantly widen the distribution of potential climate outcomes as Lowe et al. (2018) describe when showing probability distributions based on annual averages and multi-decade averages. From an impacts perspective it is useful for chapter authors to consider the time over which a threshold might be exceeded, relating this to natural climate variability where possible. There is also the potential to consider event-based

extremes, including the analysis of preparedness, based on previous analogues, e.g. as used in the National Flood Resilience Review for Storm Desmond.

As discussed in Chapter 1 (Slingo, 2021), the projected temperature and precipitation changes are broadly similar until the 2040s across all the scenarios (i.e. with similar results for RCP2.6, RCP4.5 and RCP6.0 and to a slightly lesser extent in results for RCP8.5). There is also only a small difference between the climate outcomes of these emissions scenarios even at mid-century (the 2050s). However, there is a much larger difference in the results between or within models at this time (in the 2050s). This means that the main uncertainty at mid-century is due to differences between (and within) the climate models - or to put another way – projections for the mid-century are broadly similar irrespective of the emissions scenario being assumed. This is illustrated by, for example, the 10<sup>th</sup> to 90<sup>th</sup> percentile range from UKCP09, or the 5<sup>th</sup> to 95<sup>th</sup> percentile range from UKCP18. As shown in Chapter 1 (Slingo, 2021), this leads to a considerable range, and for some parameters (e.g. summer rainfall), it can even lead to a change in the sign, from an increase to a decrease in the projected change.

As CCRA3 has the primary goal of informing adaptation, it is just as important to sample model uncertainty as it is to sample emission pathway uncertainty, especially for the medium term (2050s), which is of most interest for informing early adaptation. Authors were asked to consider the conditional probability range, specifically the 10<sup>th</sup> to 90<sup>th</sup> percentiles in the UKCP09 or UKCP18 projections, but in practice it was extremely difficult to do this in a synthesis exercise such as CCRA3, though authors considered ranges of uncertainty where relevant information was available.

Towards the late-century (2100) the RCPs diverge significantly, as shown in Chapter 1. At the end of the century (2100) there are large differences between the central estimate pathways, although the very large differences across the percentile ranges mean that there is still a large overlap between the outcomes for the different RCPs, especially for precipitation changes at the UK scale (see Chapter 1).

A further issue is that different sets of climate projections use different emissions scenarios and different approaches for implementing these in climate models. For example, UKCP09 used the SRES emissions scenarios. The 5<sup>th</sup> Coupled Model Intercomparison Project (CMIP5) projections for IPCC AR5 used the Representative Concentration Pathways (RCPs) which were defined in terms of concentrations of CO<sub>2</sub> and the resulting radiative forcing, as opposed to emissions. UKCP18 used yet another approach – it used emissions scenarios that were designed to align with the RCP concentration pathways based on a specific assumption of the strength of climate-carbon cycle feedbacks, but then made its own calculations of the future concentrations accounting for uncertainties in the feedbacks. The evidence base available to CCRA3 included studies using all these different approaches.

To account for these uncertainties in both future emissions and the responses of the climate to these emissions, whilst avoiding reliance on specific methods and hence excluding important bodies of evidence in the literature, CCRA3 characterises future climate change in terms of two pathways. These are defined as broad pathways to approximately 2°C and 4°C global warming at the end of the 21<sup>st</sup> Century (Box 2.5). This allows the use of more evidence, as it can include scenarios or emissions (or radiative forcing) and time slices, as well as warming levels. The assessment considers risks and

opportunities on the basis of studies using climate projections consistent with these 2°C and 4°C pathways. The uncertainty range across each pathway is considered as far as possible, and the Step 1 assessment uses the highest resulting magnitude score for across each scenario (across the uncertainty range) and time period. The analysis of whether the risks and opportunities are being managed across both the 2°C and 4°C pathways is considered in the subsequent Step 2.

**Box 2.5. Characterising future climate change: pathways to 2°C and 4°C global warming at the end of the 21<sup>st</sup> Century.**

In the mitigation domain, the characterisation of 2°C and 4°C warming pathways is a useful proxy for considering the costs of inaction, and the possible benefits of global emissions reductions e.g. in line with the Paris Agreement goals. However, the aim of the CCRA3 is to inform adaptation and a different framing is used. This centres on the urgency of short-term action that is needed in the next five-year period to help adapt to uncertain futures. It is therefore wrong to frame adaptation as two different alternative levels of effort that might be needed for 2°C vs 4°C global warming, but rather to identify what is needed today, given a wide range of outcomes are possible that span this range. Furthermore, there is an additional level of uncertainty associated with the climate models, quantified with percentile ranges such as the 5<sup>th</sup> or 95<sup>th</sup> or 10<sup>th</sup> to 90<sup>th</sup> percentiles from UKCP18 for each RCP or pathway. In the 2050s, the uncertainty from this uncertainty range is generally larger than between different emissions scenarios. Finally, it is stressed that for adaptation, time matters, i.e. it makes a big difference if 2°C warming is exceeded in 2050 or towards late century. For this reason, two time periods are considered, the 2050s and 2080s.

In the adaptation literature, this uncertainty is usually comprehensively sampled using decision making under uncertainty approaches. However, this approach is challenging for a synthesis exercise like CCRA3. Instead CCRA3 characterises the future in terms of pathways to approximate levels of global mean warming by the end of the century (2°C vs 4°C) and considers the uncertainty in the climate projections for each of these pathways. This allows sampling of scenario and model uncertainty. This broad approach is important because the evidence base for CCRA3 consists of studies that have used a number of different approaches, including different emissions scenarios and based on different climate models or projections. In order to make maximum use of the available evidence, an approach is used that allows evidence from a wide range of relevant sources irrespective of the details of specific scientific approaches. It is also stressed that any particular UK climate state could arise from a range of different emissions scenarios, depending on feedbacks in the climate system and the responses of regional climate processes within global-scale changes. For simplicity and clarity, CCRA3 uses two broad pathways to help sample the evidence. The lower pathway represents, approximately, the level of climate change if the goals of the Paris Agreement are met. The higher pathway represents the upper end of climate outcomes consistent with current worldwide policies.

**The pathway to 2°C global warming by 2100.** This is representative of stabilisation of global warming at approximately 1.5°C to 2.5°C above pre-industrial by the end of the 21<sup>st</sup> Century. This aligns to the goal of the Paris Agreement to limit warming to “well below” 2°C and “pursue efforts” to limit warming to 1.5°C. However, given the large uncertainties in regional climate outcomes related to any specific level of global warming, and the large overlap in the ranges of possible UK climate states consistent with 1.5°C to 2°C warming, a single Paris-compliant scenario is used in CCRA3, labelled the “2°C warming by 2100 pathway”. This deliberately imprecise definition of the 2°C pathway has the advantage of allowing the use of a large body of literature

on climate change impacts and risks under the RCP2.6 emissions scenario, which stabilises global warming in the range of approximately 1°C to 3°C at the 5<sup>th</sup> and 95<sup>th</sup> percentiles in the UKCP18 probabilistic projections (Box 2.5 Figure 1). The CMIP5 projections with the RCP2.6 concentration pathway stabilise at slightly lower temperatures (Murphy *et al.*, 2018).

**The pathway to 4°C global warming at the end of the century.** The higher pathway reaches global warming of 4°C at the end of the 21<sup>st</sup> Century (2080 - 2100). This represents the upper end of climate projections consistent with current worldwide policies, with the upper bound being the 95<sup>th</sup> percentile of the UKCP18 global probabilistic projections driven with the RCP6.0 emissions scenario (Box 2.5 Figure 1). RCP6.0 emissions are within the range of 21<sup>st</sup> Century emissions pathways consistent with current worldwide policies (Hausfather and Peters, 2020; also see discussion in the Introduction Chapter: Betts and Brown, 2021). NB “current policies” are distinct from the pledged Nationally Determined Contributions (NDCs) under the Paris Agreement, which would give lower emissions but which are not yet enacted in practice. When the RCP6.0 emissions scenario is used with the UKCP18 global probabilistic projections, 4°C is reached in 2080 at the 95<sup>th</sup> percentile of the projections, and in 2100 at around the 70<sup>th</sup> percentile.

**Box 2.5 Figure 1** Definition of 2°C and 4°C global warming pathways, compared with probabilistic projections of global warming with the RCP2.6 and RCP6.0 emissions scenarios from UKCP18 global projections (Murphy *et al.*, 2018), showing the 5<sup>th</sup>, 10<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup>, 90<sup>th</sup> and 95<sup>th</sup> percentile changes. Source for projections data: Met Office

### 2.6.2.2 Socio-economic scenarios

Future risks and opportunities are not just influenced by climate change, they are also influenced significantly in the future by socio-economic change (see Box 2.6). In theory, therefore, both should be considered in a national climate change risk assessment. These considerations are not trivial. Studies (e.g. Rojas *et al.*, 2013; Brown *et al.*, 2011) typically find that socio-economic change such as population or economic growth is at least as important as climate change in determining the overall magnitude of climate impacts in future periods. While the influence of socio-economics is often

dominant at mid-century, it is still very large in the late century, as shown by studies that compare Shared Socio-economic Pathways (SSPs) (e.g. see Hinkel et al., 2014).

#### Box 2.6. Climate and Socio-economic Change.

CCRA3 should ideally take account of socio-economic change, as well as climate change, in the assessment of future risks and magnitude. A failure to do so implies that future climate change will take place in a world similar to today. The primary drivers of modelled socio-economic change include economic growth, demographic change (population) and land-use change, but there are also a wide range of other potential factors, including policy, societal and behavioural change, that are relevant, but more difficult to consider in quantitative terms. Future socio-economic change makes a very large difference to future risks, because climate and socio-economic factors can act together as risk multipliers (although it is also possible that socio-economic change can dampen impacts). There is also another dimension when considering adaptation interventions, because socio-economic change affects adaptive capacity, and therefore adaptation can be targeted to socio-economic aspects, in addition to or as well as climate risks. However, the consideration of these issues considerably complicates analysis.

Some studies look at the effect of future climate change alone, assessing the risks on the current stock (and exposure and vulnerability). This is shown using a simplified illustration (Box 2.6, Figure 1), starting with panel 1 (far left). However, in practice, even in the absence of climate change, there will be changes in exposure and vulnerability in the future, for example with the growing population projected in the UK, as well as the projected increase in economic growth. Panel 2 shows that even in the absence of climate change, future impacts could rise due to a greater stock at risk (all else being equal). However, it is not sufficient to add climate change and socio-economic together (Panel 3) because the two acting together can lead to larger cumulative risks (Panel 4, far right), e.g. climate change acts on a larger number of people or a greater value at risk (e.g. see Rojas et al, 2013). Ideally, therefore, studies should look at the future impacts of climate and socio-economic change individually as well as together, in order to separate out the relative importance of each, though in practice this is rarely considered in national risk assessments due to the difficulty of conducting this analysis across a wide range of risks.

It is also highlighted that there is considerable uncertainty around the socio-economic scenarios themselves, which adds another uncertainty dimension to risks, especially when combined with climate drivers. This can lead to a cascade of uncertainty (see Wilby and Dessai, 2010).

**Box 2.6 Figure 1** Conceptual illustration of the impact of climate and socio-economic change, individually and in combination.

When undertaking new risk or impact assessment, it is possible to include consistent socio-economic scenarios. This approach was used in CCRA1, and it was also included in the CCRA3 research projects. However, such an analysis is impossible for a synthesis exercise such as CCRA3. Furthermore, there is very little consistency on socio-economics in the underlying literature that CCRA3 synthesises, with studies using very different approaches. Some impact studies only analyse climate change effects, i.e. they assume static socio-economic conditions. Others consider both climate and socio-economic change together, but they do this differently, e.g. some consider population growth only while others also include economic growth. Only a handful of studies split out the relative contribution of climate and socio-economic change, to allow analysis of the relative contribution of each. In theory it might be possible to use UK socio-economic projections to retrospectively adjust risk and opportunity scores, but in practice, this would be extremely challenging.

For CCRA3, authors were asked to report risks and opportunities transparently and consistently from different sources used in the evidence analysis, and to document the assumptions on socio-economic change (e.g. whether UKCP09 and UK socio-economic scenarios are used, or SSP scenarios, and which parameters were considered). However, this does not address the challenge of consistently scoring risks and opportunities in the magnitude tables. Ideally, all risks and opportunities should either consistently include or exclude socio-economic factors.

For CCRA3, the recommendation was to initially identify and score the total risk (the combination of climate and socio-economic change) where possible, on the basis that it is the total risk that the UK has to adapt to, provided climate change is a major factor<sup>7</sup>, for example, the combined total effect of increased population and increased flood hazard. The exception to this is when a risk is dominated by other factors and not climate, e.g. as is the case for air pollution. In this case, authors were asked to score the incremental risk from climate change (and in the subsequent adaptation step, to only consider if the risks of additional climate-related risks were not being managed).

However, it was also recommended to split out (where possible) the contribution from climate change versus socio-economic change. In cases where risk information is only given in terms of the climate change signal alone, authors were asked to give some consideration (for future periods) of the potential change in risks (or opportunities) that might arise from the combination of socio-economic change. Most importantly, authors were asked to be transparent and document exactly what had been used, i.e. whether climate change only, or climate change and socio-economic change, and if the latter which metrics.

To help inform CCRA3, the CCC commissioned a new set of UK socioeconomic dimensions from Cambridge Econometrics (CE) (2019) as one of the CCRA3 research projects. These provided consistent projections out to 2100 for the following priority indicators: Population; Gross Domestic Product (GDP), Gross Value Added (GVA); Employment; Labour productivity (calculated from GVA

---

<sup>7</sup> A different issue arises if the CCRA3 Evidence Report was to be used to provide detailed information on the benefits of domestic mitigation policy, as part of global policy commitments towards the Paris Agreement. In this case, the focus is on the difference in the total risk between alternative climate and socio-economic outcomes, e.g. between 2 and 4°C, which provides the net benefit of mitigation. However, when reporting the marginal risk of climate change impacts for an individual scenario, this should - strictly speaking - only include the marginal increase over and above the socio-economic counterfactual, as only that marginal increase is directly attributable to climate change.

and employment projections); Land use; and Households occupancy rate. It is noted that this set of data is not a set of UK socioeconomic scenarios and is not aligned to the IPCC Shared Socio-economic Pathways (SSPs). Instead, the CE projections provide a central estimate along with an upper and a lower bound estimate for each of the indicators, to use across the CCRA analysis where appropriate. The low and high socio-economic data presented are based on the ranges from the national data sets, e.g. around UK population projections. This mirrors the approach used in previous CCRA3s, which have focused on stand-alone national projections, in order to make sure that these are compatible with official Government projections. The CE projections do consider some mitigation elements for energy use, where the central scenario is based on the National Grid FES 'Two Degrees' scenario, and for land-use, where the high scenario includes an ambitious mitigation policy. It is noted that socioeconomic dimensions related to the adoption of the Net Zero emissions target was not factored into the CE report as quantified scenario data was not available, and does have some major implications, see section below. The CE socio-economic data sets were used in the CCC commissioned CCRA3 research projects on floods and water availability. However, they could not be used to adjust existing studies in the literature for the Technical Report chapters, because this would have required the primary studies to have presented future impacts for socio-economic change alone.

A final issue on the socio-economic scenarios is the linkages with the international climate change literature. In earlier studies (circa the time of the IPCC 4th Assessment Report), there was a set of self-consistent and harmonised scenarios for both socio-economic and climate change (the SRES scenarios). Future socio-economic pathways and associated Greenhouse Gas (GHG) emissions were first assessed, then fed into global and regional climate models.

For the IPCC 5th AR, a new family of scenarios was defined, the Representative Concentration Pathways (the RCPs) (van Vuuren et al., 2011). These include a set of four climate (forcing) pathways (now extended to five), which cover futures that are broadly consistent with the 2°C goal through to high-end (>4°C) scenarios. However, these were originally not aligned to specific socio-economic scenarios (as in the SRES). The RCPs were designed to be combined with a set of global Shared Socio-economic Pathways (SSPs) (O'Neill et al., 2014). The SSPs provide a set of socio-economic data for alternative future pathways. Five alternative SSPs are currently provided (SSP1 to SSP5), each with a unique set of socio-economic data and assumptions (available for each country). The SSPs are presented along the dimensions of challenges to mitigation and adaptation. This provides the flexibility to combine alternative combinations of future climate and socio-economic futures. Combining RCPs and SSPs gives a large matrix of combinations (though not all RCP-SSP combinations are considered possible, Riahi et al., 2017). This amplifies the uncertainty envelope, and there is a need to sample possible future combinations to make analysis manageable. The RCP-SSP approach has been used in much of the International climate literature when undertaking new impacts analysis (e.g. see IPCC 2018a; IPCC, 2019). The SSPs have not been used in CCRA3, as this is not possible in a synthesis exercise, and were not considered in the CE study. However, there has been recent work that has developed Shared Socio-economic Pathways for the UK (UK-SCAPE: SPEED project) (Pedde et al, 2020). These provide downscaled and enriched versions of the SSPs for the UK as narratives and tables of trends and provide additional relevant information, which could be used as an underpinning dataset for CCRA4. These are summarised in Box 2.7 below: these descriptions are from the SPEED project itself and are presented as an illustration of this type of approach: they

were not used in CCRA3. There are also similar SSPs that have been developed specifically for Scotland (Kok et al., 2016).

#### **Box 2.7. Example of Shared Socio-economic Pathways for the UK.**

The UK-SCAPE project has developed UK SSPs. The summaries of these are presented below (Pedde et al, 2020) as an example of the development of UK specific SSPs. We stress the descriptions given below are taken from the study itself.

**UK SSP1-Sustainability.** A shift towards sustainability is triggered by natural disasters, the vulnerability of many job sectors, and worsening standards of living that are perceived to be connected to environmental degradation. Local green political networks and initiatives for change emerge, leading to strong support for regionalisation. New legislation integrates green development in lifestyle changes and in the technology, economic and energy sectors. Sustainable agricultural intensification, facilitated by effective “polluter pays” legislation, and international cooperation enable the UK to reduce its impacts from the externalities of agro-food systems. A UK-wide “green race” delivers the policies and technologies that maximise sustainability and is established across countries. Collaboration domestically and internationally plays a key role in the green race, ensuring technologies, ideas and projects are shared to gain mutual benefits. By 2100, the UK becomes a fully functional circular economy.

**SSP2-Middle of the Road.** Key public services, such as the health and pension sectors, reach a critical point prompting reform through public-private partnerships. Public-private partnerships also push forward technological development and investments in other sectors, such as transport, energy, IT and infrastructure. While the UK continues to enjoy overall economic growth, social inequalities increase and are countered by the introduction of a basic income and new working rights. A series of shocks, such as crop epidemics and severe water shortages, leads to strong policy responses that introduce Payment for Ecosystem Services schemes to address unsustainable food systems, pollution and biodiversity loss. Both urban and rural planning becomes highly regulated.

**UK-SSP3-Regional Rivalry.** With job losses and barriers to trade, the government lifts EU and UK environmental regulations to allow access to a wider supply of domestic natural resources. The UK increasingly closes its borders and invests in defence. Immigration from European and non-European countries decreases, but internal migration increases because people move around the UK in search of job opportunities which become concentrated in the major cities. The high competition for jobs leads to an exploited workforce with low salaries. With a reduction in personal income and the redistribution of public spending towards the defence sector, health prevention and treatments decrease and death rates from ill health increase. Around 2040, Scotland becomes independent from the UK, with the other nations following quickly afterwards. With increasing socio-economic barriers, conflicts arise, markets shrink and informal economies increase. With high levels of corruption, criminality is widespread across society and criminal bands substitute themselves for former institutions. Across the (former) UK, a return to self-subsistence lifestyles is widespread.

**UK- SSP4-Inequality.** In order to boost economic growth public support for radical action towards novel development strategies increases. A National Strategy Development Plan is created to foster business and economic opportunities in green energy and technological development through opening up access to land resources. As businesses and technology flourish, peer-to-peer

networks for storing and distributing digital information become popular means for businesses to bypass centralised financial regulations and accumulate wealth. Society becomes increasingly polarised and the North South divide widens. The divide is accentuated by the lack of government intervention: the welfare state has been slowly eroded until its end in the 2060s. Lack of a stable income and poor living conditions means that the vast majority live through committing minor crimes, while a small proportion of rich elite control economic and natural resources.

UK-SSP5-Fossil-fuelled Development. Reduced public support for carbon taxation and taxes to finance green transformation of infrastructure, lead to continued demand for cheaper and more readily available fossil fuels. Strong development in domestic manufacturing is supported by the discovery of shale gas, which leads to reduced energy costs. Increasing public investments in shale gas production in northern England heavily contributes to the removal of the North-South divide. The economy increases exponentially and welfare increases. Large increases in population lead to rapidly expanding “city states” and massive urban sprawl. Large-scale environmental degradation is initially masked using technological solutions. However, environmental tipping points are reached by the end of the century ultimately leading to food shortages.

The scenarios present trends for a number of key socio-economic drivers, for various categories (e.g. demography and society) and elements (e.g. population, urbanisation) for each SSP above. These scenarios are being further developed under the UKRI-funded UK Climate Resilience Research Programme, also being led by Cambridge Econometrics.

### 2.6.2.3 Net Zero

During the period that the CCRA3 was undertaken, the UK Government adopted a Net Zero greenhouse gas emissions target for 2050. The 2008 Climate Change Act was amended from *‘it is the duty of the Secretary of State to ensure that the net UK carbon account for the year 2050 is at least 80% lower than the 1990 baseline’* (net emission of CO<sub>2</sub> and net emissions of other targeted GHG), to *‘at least 100% lower’*. The Scottish Government also set a net-zero target date of 2045 through the Climate Change (Emissions Reduction Targets) (Scotland) Act 2019 (SP, 2019). The Welsh Government has announced a 95% reduction in greenhouse gas emissions by 2050 with an ambition to reach Net Zero (WG, 2019). At the time of writing, Northern Ireland had not yet adopted a target but this was under consideration.

This had important implications for the future baseline socio-economic scenarios in England and all DAs as well as mitigation-adaptation linkages. However, at the time of the CCRA3 analysis, there was no published Government studies or policy announcements on how this Net Zero target will be achieved. To consider this change, an additional step was included in the second round of the CCRA3 risk and opportunity scoring. This added two questions at the end of Step 1, for consideration at the level of each individual risk and opportunity. These were: 1) Is the Net Zero target likely to increase or decrease the magnitude of the CCRA3 risk/opportunity, e.g. due to the implementation of measures to achieve the target, and associated changes in the receptor the hazard is acting on? 2) Could the climate change risk or opportunity make the net zero target easier or harder to achieve? Given the current state of evidence (on Net Zero), these questions were addressed qualitatively. To inform these answers, CCRA authors were asked to draw on the techno-economic scenarios of the Net Zero report published by the CCC (CCC, 2019b). These scenarios illustrate ways in which extensive decarbonisation of the UK economy could occur by 2050 (to demonstrate that a Net Zero

emissions target by 2050 is plausible). However, these scenarios are not prescriptive on which scenario is favoured, or which policies would need to be developed to achieve the goal.

It is stressed that the CCC scenarios are technical in nature and the Net Zero target does not mean that the UK is on a SSP1 sustainability trajectory (see Box 2.7), not least because the SSPs relate to both mitigation and adaptation challenges and need to be seen in the context of global scenarios.

#### 2.6.2.4 Low likelihood, high impact scenarios

Although 4°C global warming in the 2080s is currently assessed as the fastest rate of warming consistent with current worldwide policies and a reasonably likely range of responses of the climate system, application of the Precautionary Principle motivates consideration of more extreme scenarios. The possibility of emissions growing at higher rates cannot be ruled out, and neither can the possibility of strong feedbacks in the climate system, even if these are considered unlikely.

Moreover, there may be critical thresholds at which large-scale components of the Earth's climate system, at least sub-continental in scale, switch to a qualitatively different state due to a small perturbation, and which may be irreversible (Lenton et al., 2008; Lenton et al., 2019). A number of these are particularly important for Europe (Levermann et al., 2012). Examples include Greenland and Antarctic ice sheet deglaciation, which could become irreversible even if warming is stabilised, accelerated loss of ice from the Antarctic ice sheet, collapse of the Atlantic Meridional Overturning Circulation (AMOC), and accelerated carbon release from forest dieback or thawing permafrost. The latter would affect the rate of global warming. Several of these are discussed in Chapter 1, and Good et al. (2018) provides a review of recent literature since the IPCC 5th assessment report.

In previous CCRA, there was some consideration of extreme or high-end risks associated with a High++ scenario, and this was included again in CCRA3. However, in CCRA3, there is also more attention placed on additional low-likelihood, high impact scenarios and events. These include more extreme national to local high-end risks (sometimes called tail-end), higher warming scenarios (that lead to more than 4°C global warming by the 2080s), and global Earth System tipping points or tipping elements. These have not been included in the urgency scores analysis, due to the different nature of these outcomes, but they have been considered separately.

For individual risks and opportunities, authors were asked to capture and report any information on impacts of low likelihood, high impact risks in the evidence base. This could be new assessments of High++ scenarios, or evidence of impacts from projections that warm so rapidly that they reach 4°C earlier than the 2080s. The latter includes a large proportion of the UKCP18 projections with RCP8.5 emissions, and approximately the fastest-warming half of CMIP5 projections using RCP8.5 concentrations. The categorisation of different projections into the main analysis for the urgency scores versus Low Likelihood High Impacts scenarios is shown in Box 2.8. To help this, the question from the US 4th National Climate Assessment (USGCRP, 2018) was considered, i.e. 'how bad could things plausibly get?' This information was not used in the magnitude score and was reported separately.

**Box 2.8. Categorising climate projections as “Main Analysis” or “Low Likelihood High Impact”.**

The upper boundary of the “main” projections for CCRA3 is defined by the earliest time of reaching 4°C global warming with emissions consistent with current policies (see Box 2.5). Impacts and risks studies that use projections that reach 4°C global warming between 2080 and 2100 are therefore within the “main” analysis as part of the higher warming pathway and are used for the magnitude scoring. Impacts and risks studies that use projections that reach 4°C global warming before 2080 are in the “low probability high impact” category. However, in some cases, information from the latter can still be used to inform assessments in the main analysis, e.g. by comparing results at a particular Global Warming Level (e.g. 4°C) to assess whether climate hazards or dynamical processes at a particular warming level are different in new projections such as UKCP18 compared to older projections such as UKCP09. This method works for some hazards (e.g. extreme precipitation) but not others (e.g. sea level rise).

*The following projections were considered eligible for direct inclusion in the main analysis:*

- UKCP18 projections driven by RCP6.0 emissions;
- CMIP5-based impacts studies using the RCP6.0 concentration pathway;
- Many of the UKCP09 “medium” (A1B) scenario – up to approximately the 75<sup>th</sup> percentile of the probabilistic projections (see Box 2.8 Figure 1) and the majority of the 11-member RCM Perturbed Parameter Ensemble;
- Results from the lower percentiles of probabilistic projections with the UKCP09 “high” (A1FI) scenario (see Box 2.8 Figure 1 below)
- Some CMIP5-based impacts studies using the RCP8.5 concentration pathway, including those using central estimates of the ensemble, and individual models which reach 4°C in 2080 or later (see Box 2.8 Figure 2);
- Subsets of the UKCP18 probabilistic projections driven by RCP4.5, RCP6.0 or RCP8.5 emissions that reach 4°C close to 2100 (see Sayers et al., 2020; Arnell et al., 2021);
- Subsets of the UKCP18 projections driven by RCP6.0 or RCP8.5 emissions that reach 4°C between 2080 and 2100, i.e in the upper percentiles of the RCP6.0 probabilistic projections or lower percentiles of the RCP8.5 probabilistic projections.

**Box 2.8 Figure 1** Comparison of global mean temperature projections (5<sup>th</sup> to 95<sup>th</sup> percentile ranges) from the UKCP18 probabilistic projections driven by RCP6.0 emissions with the UKCP09 probabilistic projections driven by SRES B1 (“low”), A1B (“medium”) and A1FI (“high”) emissions. Source for projections: Met Office

**Box 2.8 Figure 2** Comparison of projected global mean temperature changes (5<sup>th</sup> to 95<sup>th</sup> percentile ranges) from the UKCP18 global probabilistic projections driven by RCP6.0 emissions with the CMIP5 multi-model ensemble driven by RCP8.5 concentrations. Sources for projections: Met Office, KNMI Climate Explorer <https://climexp.knmi.nl/start.cgi>

*The following were considered part of the low likelihood, high impact (LLHI) analysis:*

- CMIP5-based impacts studies using the RCP8.5 concentration pathway with *some* of the CMIP5 global models (those that reach 4°C before 2080 – roughly half of the models);
- A subset of the UKCP18 projections driven by RCP8.5 emissions that reach 4°C before 2080, i.e. in the middle and upper lower percentiles of the RCP8.5 probabilistic projections.

Use of projections that reach 4°C before 2080

In some cases, information from projections that reach 4°C global warming earlier than 2080 were used to inform the main analysis by applying the results to a later time (e.g. HRW, 2020). A change in climate hazard at, say, 4°C global warming in 2070 could still be representative of a change in climate hazard at 4°C global warming in 2090, if the associated regional changes in climate quantities are known to depend primarily on the instantaneous magnitude of global warming and are not strongly dependent on the rate at which this magnitude is reached (Wartenberger et al., 2017; Barring and Strandberg, 2018). This allows a wider range of evidence to be included, but needs to be used with care, as it is not always scientifically appropriate – for example, this approach would not be appropriate for impacts of sea level rise, which responds to rising global temperatures over very long timescales.

Alongside this, a cross-chapter approach was taken to characterise low likelihood, high impact risks. These were discussed in Chapter 1 (Slingo, 2021). This included new information from the UK Met Office.

This information was included in an overall narrative for each chapter. It was also translated into a separate watching brief for Government for low-likelihood, high impact events and scenarios.

Finally, it is noted that the low-likelihood, high impact scenarios above relate to the earth system. There is a new emerging literature on socio-economic tipping points (van Ginkel et al., 2020), i.e. where the tipping point arises in the socio-economic system. The evidence on these extremes is more limited, which limits a more formal analysis, but some consideration of other large-scale, potentially catastrophic risks was considered in the watching brief for Government.

#### 2.6.2.5 Distributional effects and inequalities

As identified in CCRA2 (Street et al., 2016), there is strong evidence that climate risks and adaptation measures will affect people differently, depending on their social, economic and cultural environment. People and communities facing both social vulnerability and exposure to climate hazards are likely to be the worst affected, and low-income households will be particularly affected through negative effects on the cost of living, and because they have fewer resources with which to respond (JRF, 2016).

There are many different approaches for considering these issues, with elements that consider hazard, exposure and vulnerability (including adaptive capacity). In CCRA3, they are considered in terms of environmental health inequalities, recognising that socioeconomic and demographic inequalities can be expressed in relation to factors such as income, education, employment, age, sex, race/ethnicity and specific locations or settings. The report is primarily focused on how these factors affect the risk of being exposed, but also that inequalities are also caused by social or demographic differences in vulnerability/susceptibility towards certain risks.

Many environmental health inequalities, particularly where they are linked to socioeconomic variables or gender, also represent “inequities” because they are unfair and unjust. The root causes of these inequalities are complex, but involve issues of distributive justice and procedural justice (see also the definition of environmental justice, USEPA, 2020), i.e. risks are not evenly distributed within societies and populations, and different population groups may have different opportunities to influence decisions affecting their environment.

In CCRA3, chapters were asked to discuss risks or opportunities across affected populations, by type of individual, and regional dimension, and assess inequalities in relation to the impact of climate change (climate risks) (Step 1) and those generated by any relevant adaptation responses (Steps 2 and 3).

#### 2.6.2.6 Monetary valuation

The requirement statement for CCRA3 from Defra and the DAs included a request for an analysis of current and future risks and opportunities in monetary terms. This type of valuation (monetisation) is a standard part of government economic appraisal, as set out in the HM Treasury Green Book (HMT, 2018). It is based on the principles of welfare economics – that is, how the government can improve social welfare or wellbeing.

The aim of this sub-task was therefore to monetise current and future risks and opportunities (the results of Step 1a and also Step 1b below) as far as possible, expressing these in terms of the effects on social welfare or wellbeing (HMT, 2018), i.e. for society overall, as measured by individuals' preferences using a monetary metric. This values market and non-market impacts, and includes consideration of environmental, economic and social costs and benefits, not just financial costs. It is recognised, however, that it is much more challenging to value some risks, such as those in the natural environment theme. The valuation was undertaken for individual risks and opportunities.

In CCRA1, an indicative monetary valuation was undertaken. This used a consistent approach, drawing on the underlying quantitative and semi-quantitative assessment of individual risks and opportunities from the study (HRW, 2012a). It used a standardised approach for valuation, based on the guidance from HMT Green Book and from individual Government Department appraisal, and estimated the annual average damage for future time periods for the alternative UKCP09 projections for each individual risk and opportunity. Values were presented without discounting<sup>8</sup>, in order to facilitate direct comparison over time and between sectors. The monetary valuation of risks and opportunities was not undertaken in CCRA2.

For CCRA3, the method used for monetary valuation mirrors the approach used in CCRA1, and aligns to existing Government appraisal. The valuation was undertaken by a cross cutting team, working with the chapter authors, looking at risks and opportunities individually in terms of annual average effects. These estimates are presented in a separate report, but were fed back into the current and future magnitude scores for each risk or opportunity.

As CCRA3 is a synthesis of existing research, quantification of monetary values is much more challenging than in CCRA1, due to a lack of quantified future impacts for different scenarios in many cases. In CCRA1, a consistent (semi-) quantitative analysis was undertaken for each individual risk as part of a detailed impact assessment, using harmonised climate model projections and socio-economic scenarios. In contrast, CCRA3 relies on existing studies (evidence) for each risk and opportunity, but this means there is little consistency due to differences in primary studies in the choice of climate and socio-economic scenarios, methods used, granularity (national/local), etc. This makes it much more difficult to produce directly comparable results. As a result, in CCRA3 the monetary valuation was primarily indicative, providing information on the order of magnitude of potential impacts or benefits, in line with the magnitude scoring set out in Table 2.2. Where possible, the valuation analysis imposed consistent practice through use of a common base year for prices, without discounting (as for CCRA1, see above) in order to facilitate direct comparison over time and between sectors. For some risks, direct economic cost estimates were already available (primarily floods). For some quantified risks, unit monetary values from existing Governmental appraisal guidance were applied. Where no quantitative information was available, estimates of the order of magnitude of the economic costs was made based on available information and expert judgement. As well as the estimated values, a consideration was made of any important distributional costs or benefits, in line with HMT Green book guidance (HMT, 2018). It is stressed

---

<sup>8</sup> It is noted that the economic costs of climate change, and the use of these estimates in subsequent policy analysis, such as the social cost of carbon or adaptation policy cost-benefit, should discount. While the choice of discount rates has been a source of considerable disagreement in the literature, there is guidance set out in the Treasury Green Book (HMT, 2018), and supplementary guidance on intergenerational discount rates (HMT, 2008).

that due to the use of a synthesis approach and evidence gaps for many of the risks, it was not possible to provide an aggregate impact (of climate change) in the UK (i.e. the total costs of climate change, from all risks and opportunities, expressed as an equivalent % of GDP).

The potential to consider the economic costs on natural capital from climate change in CCRA3 was considered, but was not possible to undertake comprehensively as it was limited by the availability of evidence on the quantitative impact (or benefit) of climate change on natural capital – as well as the valuation of changes in natural capital.

### 2.6.3 Task 1c Assessing Possible Thresholds and Lock-in

As highlighted earlier (see section 2.3), CCRA3 has made more attempt to introduce adaptive management thinking. This included consideration of thresholds and lock-in risks.

Authors were asked to identify potential major thresholds and if changes might arise under different climate futures, notably with respect to the pathways to 2°C and 4°C global warming by the end of the century, including consideration of uncertainties in regional changes. This analysis was supported by a CCC commissioned CCRA3 research project on quantifying known threshold effects in the natural environment (Jones et al, 2020). The identification of thresholds was used to consider a possible change in the magnitude score, for example when it involved a major step-change in the risk (or opportunity), although the primary use was to consider whether current adaptation plans are sufficient and whether there would be benefits from additional adaptation (i.e. Steps 2 and 3).

For lock-in, CCRA authors were asked to identify any potential for lock-in (see section 2.3) over the next five years when considering risks and opportunities. This was focused on identifying actions or decisions that could potentially increase future risk or vulnerability that are also difficult or costly to reverse later (quasi-irreversibility / path dependency). This can be from an i) action or decision taken that is 'business-as-usual', ii) from a lack of an action or decision, or iii) from a maladaptive action or decision. This introduces the concept of path dependency. Ideally, the identification of lock-in risks would involve a quantified analysis of the impacts (and costs) of inaction, though is difficult to do in a synthesis exercise such as CCRA3. Similarly, authors were asked to identify decisions or actions in the next five years that needed to be taken to enable opportunities to be realised. The temporal focus of lock-in is on the short-term, particularly the next five years (consistent with the adaptation programme period), while noting these risks or opportunities from the lock-in emerge in the longer-term. While the analysis of lock-in was identified and reported in Step 1, it was used when considering the urgency scoring in Step 3.

### 2.6.4 Task 1d Investigate Cross-Cutting and Interdependencies

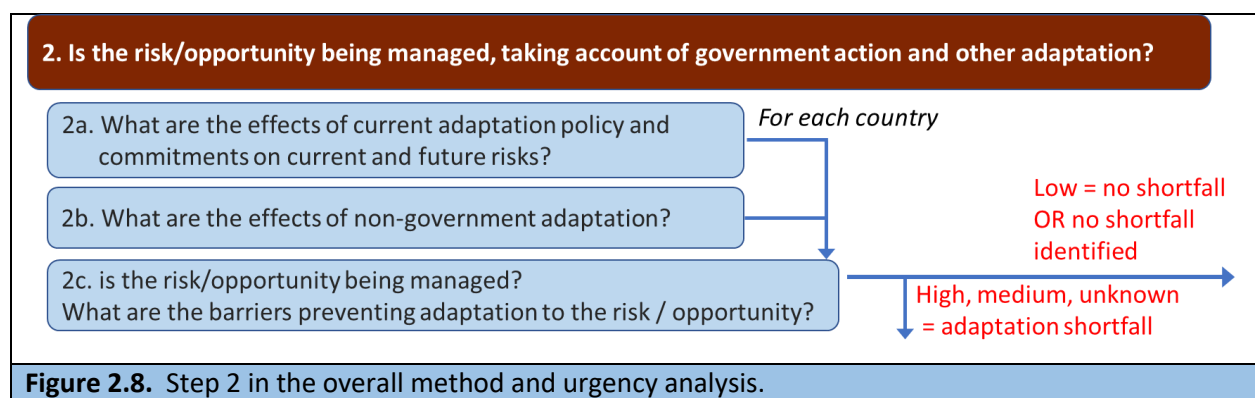

CCRA2 included a dedicated chapter on cross-cutting issues (Street et al., 2016). This considered two types of cross-cutting issues: first, cross-cutting issues related to risks which include interacting risks (hazards with multiple impacts), the consequences of interacting risks (knock-on effects) and distributional risks (how risk affects people differently); and second, cross-cutting issues related to adaptation.

For CCRA3, interdependencies, cascading risks and cross-cutting risks were considered and documented for each risk and opportunity. This analysis was supported by a CCC commissioned CCRA3 research project on Interacting risks in infrastructure, the built and natural environments (WSP, 2020). The project created 12 interlinked systems maps showing principal interactions within and between the three sectors. The analysis of interacting and cascading risks, as well as the possibility of combinations of hazards (Hillier et al., 2020) was subsequently considered in the magnitude score for each individual risk and opportunity, with authors given the option to increase the magnitude score based on evidence (using the magnitude in Tables 2.2 and 2.3).

## 2.7. Step 2 Assess Current and Planned Government and non-Governmental Adaptation

The second step in the CCRA3 Technical Report method (Figure 2.8) assesses the influence of current or planned adaptation in reducing current and future climate change risks, or responding to potential opportunities. This provides an analysis of whether the medium, high or unknown risks and opportunities identified in Step 1 are already being managed. The objective is to identify the benefit of current and announced adaptation policy in reducing risks or enabling opportunities. It also considers what might happen in the absence of further Government action, and thus whether there is a justification for additional action.

These steps are described in more detailed below.

### 2.7.1 Task 2a Analysis of Current, Planned Government Adaptation

The first task is focused on assessing how current and planned adaptation might manage the risks identified (in Step 1). The tasks involved a mix of qualitative and/or quantitative assessment methods. Authors were asked:

- To assess the policy landscape for adaptation and identify existing policies and commitments (including current as well as announced policies).
- To review and assess how far current planned adaptation action is reducing current risks or fully realising current opportunities. For risks, this included consideration of how adaptation is reducing exposure, decreasing sensitivity or enhancing adaptive capacity.

- Authors were also asked to consider and document what effect adaptation actions have had since the last CCRA, i.e. between 2012 and 2019.
- To review and assess how planned adaptation, and announced plans, could reduce future risks or realise opportunities, as well as the potential for maladaptation from these plans.

This analysis was undertaken for each country. Additional information is given below.

The starting point was to understand the organisational responsibility and governance arrangements for climate risks and adaptation (noting the two may differ), as well as to identify the current and announced organisational objectives and policies/strategies of relevance for climate risk and opportunities (non-climate and climate). This considered Government strategies and policies (overall, and in the relevant sub-programmatic areas) both in relation to specific existing and announced climate or resilience policy (National Adaptation Programme (NAP1 and NAP2) and the adaptation programmes of the DAs) but also broader policy interventions that could reduce climate risk or vulnerability. It also considered existing standards and guidance (mandatory and voluntary).

This task then considered how far existing policies and interventions are managing current risks, or fully realising opportunities. CCRA3 authors were asked to consider what effect adaptation actions have had on the level of current risks since the CCRA2 assessment (and indeed since CCRA1). Following from Step 1, it was also important to consider if current government action is addressing lock-in risks.

The analysis then looked forward, and considered how far existing policies and interventions, including announced planned adaptation policies and strategies, are managing future risks or opportunities. This effectively considered a current 'adaptation policy scenario', which included a consideration of adaptation policy objectives (and targets), the planned activities and outcomes, and the possible effect on reducing risks (or realising opportunities). This is a key part of the analysis, but it is challenging because Government targets on adaptation are often quite generic (i.e. they may not be quantitative, or defined in SMART terms [Specific, Measurable, Achievable, Realistic and Timebound, see National Audit Office, 2019]). Furthermore, there is often no quantified analysis (in published adaptation policies and strategies) on the anticipated level of risk reduction and thus the benefits of adaptation policies and strategies (Watkiss et al., 2019). In short, there is often not the quantitative evidence presented in adaptation policies to know the extent to which future risks are being reduced or opportunities realised. Further, there are important differences in how adaptation objectives can be set, as well as the framing used in policy, that have a major influence, involving the absolute or relative level of risk reduction, as well as the trade-off between adaptation costs and benefits, as well as residual risks. Further information is presented in Box 2.9.

For adaptation to future risks, the analysis considered the degree to which existing and announced policies would help adapt across all scenarios (2°C and 4°C future warming scenarios by 2100 globally) including uncertainty. Initially, authors were asked to consider whether adaptation was sufficient to manage risks across the probability range, specifically the 10<sup>th</sup> to 90<sup>th</sup> percentiles in the UKCP09 or UKCP18 projections. However, there was rarely the evidence to undertake such an analysis in practice, and authors were asked to consider the ranges of uncertainty, as far as possible.

In the case of water availability and flood risk, a current adaptation policy scenario was calculated in the accompanying CCRA3 research projects and was used directly in the relevant chapters in the Technical Report to help to consider the level of risk reduction.

Authors were also asked to discuss whether the proposed adaptation (in policies and strategies) involves potential trade-offs or maladaptation. They were also asked to consider the distributional consequences or inequalities inherent in existing or planned adaptation.

**Box 2.9 Adaptation Objectives.**

There are many existing adaptation policies in place, as reported in the NAP2 (Defra, 2018) and the 25 Year Environment Plan (25 YEP; HMG, 2018) and the Adaptation Plans of the DAs. These form the basis for generating a current adaptation policy scenario, but it is often challenging in practice to assess the actual benefits of these policies because many of them are not specific in terms of objectives (Watkiss et al., 2019). Many of the targets in the 25 YEP and NAP2 are quite general, e.g. they set a general goal for reducing risks or enhancing resilience, but do not include a specific stated objective and outcome, which makes it difficult to understand what level of adaptation benefit the policy is meant to achieve. This is important because there are different policy approaches and objectives for managing climate risks, and there is not a consistent approach used across Government for managing current risks, let alone for the future. To illustrate this by way of an example. In a hypothetical scenario of coastal protection, there are a number of potential choices for setting an adaptation objective:

- Maintain existing adaptation infrastructure. This involves additional maintenance costs in the future, but involves no additional enhancement of existing infrastructure or any additional adaptation infrastructure.
- Maintain current (policy) objectives. This aims to maintain a constant relative risk. For example, where a clear standard is set, e.g. an acceptable level of risk protection such as a 1 in 100 year level, this can be maintained over time. However, this involves cost implications, because additional infrastructure (increased costs) are projected to be needed in the future, to maintain the same (1 in 100) level of protection under a changing climate with higher risks. Importantly, maintaining the status quo will require additional action. Related to this, it cannot be assumed that Government will maintain existing objectives, unless there is an explicit policy commitment to also increase expenditure (on flood infrastructure).
- Maintain current levels of protection based on damage levels. This aims to maintain a constant absolute risk. While this looks similar to above, it involves much higher levels of protection, because of rising socio-economic change and increased value at risk, as well as increasing climate change. It therefore involves higher costs (though it also provides higher benefits).
- Maintain the (economic) optimal level of adaptation, where the costs and benefits of further protection are considered and the optimal response introduced. This usually involves lower levels of adaptation, because it avoids high-cost adaptation investments with lower benefits, but has higher residual damages when compared to risk-based approaches above (although these higher risks could, for example, be addressed through insurance). In practice, it is almost impossible to know the optimal level of adaptation because of uncertainty (though it is possible to consider dynamic optimality (Eijgenraam et al., 2013) or optimal-like responses under uncertainty).

Critically, each of these choices involve very large differences in the way that risks are managed, as well as the benefits of further action (and thus adaptation costs and benefits). These objectives would normally be compared to a counter-factual option to do nothing (to live with the risk), and would lead to the subsequent consideration of different types of interventions, e.g. whether to protect or retreat. It is highlighted that further consideration of objectives would be useful, including consideration of public risk preferences on these issues.

In theory, the analysis of planned adaptation should also take account of alternative socioeconomic futures, because these will affect exposure, residual impacts, etc. and thus the effectiveness of

adaptation. They might also bound the national and regional availability of resources for adaptation. In practice it is very difficult to assess this except where there is very detailed quantified information available. Adaptation can also – itself – lead to lock-in, linking back to the lock-in issues identified in Step 1.

A similar approach is used to assess opportunities, although there are some important differences. For opportunities, there is a need to consider spontaneous and non-government planned adaptation first (Task 2b, below) and assess how far these realise the potential benefits or whether there is a potential shortfall. In the case of the latter, the analysis has to then consider if Government action is in place to help realise opportunities, e.g. to create the enabling environment to enhance potential benefits (of climate change). If not, then the opportunity is considered not to be fully managed. In theory, this could mean that the magnitude score of a potential opportunity could be high, but current actions are only likely to deliver a low or medium score. This is different to the scoring of risks (where a low magnitude assumes no additional action is needed). The analysis of whether opportunities are being managed was primarily qualitative, based on the evidence, expert judgement and discussion with Government and stakeholders.

The analysis of planned adaptation also considered the potential synergies and trade-offs with mitigation. This has an important linkage to the Net Zero target. As highlighted above, it was not possible to use Net Zero as a new business as usual scenario, because at the time the evidence review was undertaken there were no announced plans or policies on how this would be achieved. For this reason, CCRA authors were asked to consider the synergies and trade-offs between adaptation and mitigation in Step 3, as part of Net Zero considerations (see later discussion).

#### 2.7.1.1 Adaptive capacity

Previous studies, including CCRA1, have highlighted the importance of adaptive capacity in adaptation. However, there are different definitions of adaptive capacity. From one perspective, it is a part of the IPCC Core Concepts and linked with vulnerability (see Step 1). However, there is a separate aspect of adaptive capacity that relates to the goal of CCRA3 and the capacity of planned Government action to respond to the risks identified. This emphasises socio-institutional and organisational aspects, i.e. associated with the ‘process of adaptation’ at organisational and/or structural (sector) level (see Box 2.10). This element sits within Step 2 of the method.

In CCRA1, Ballard, Black, and Lonsdale (2013) defined this form of adaptive capacity as *the ability of a system to design or implement effective adaptation strategies to adjust to information about potential climate change (including climate variability and extremes), to moderate potential damages, to take advantage of opportunities, or to cope with the consequences*. In this definition, ‘adaptive capacity’ is the capacity to take effective adaptation actions, i.e. the extent to which organisations and individuals are able to identify climate risks and make well-informed, long-term decisions that could make them more resilient to the impacts of climate change. A survey was undertaken of the level of organisational and structural capacity in different sectors. This survey was not repeated in CCRA2, and was not included in CCRA3: this represents a missed opportunity to capture progress over time. It is noted that there would be benefits from a more explicit consideration of adaptive capacity in CCRA4.

**Box 2.10 Adaptive Capacity.**

Previous work on adaptive capacity (Ballard, Black, and Lonsdale, 2013) in CCRA1 differentiated adaptive capacity into two distinct components:

- Organisational adaptive capacity (OAC): a measure of the current ability of organisations within the sector to undertake effective adaptation actions in response to climate change. This considers the level of capacity of the organisation, i.e. does it have a climate risk management or adaptation plan through to whether it is planning strategically and has implemented adaptation.
- Structural adaptive capacity (SAC): a measure of the systemic factors currently at work within the sector that affect its ability to adapt to climate change. These consider the sector's complexity, typical decision lifetimes (short or long), and the extent of activity providing potential opportunities for undertaking adaptation actions.

In sectors where SAC is low (e.g. because the sector is highly complex or decision lifetimes are typically very long), a correspondingly higher level of OAC will be needed to compensate and so enable the sector to adapt successfully to the impacts of climate change. Underlying this is the assumption that capacity develops progressively, i.e. that organisations start off less effective, but grow capacity through learning, thus barriers that apply at early stages are different to those that apply when organisations improve. There are also some studies that have reported on success factors for building capacity for adaptation (Ballard, Black, and Lonsdale, 2013; Ballard, Bond, et al., 2013; Frontier Economics, 2013).

There is also a much wider literature on adaptive capacity that includes many more components and aspects. These are contingent on the wider enabling environment, such as access to data, scientific and technical knowledge, institutions, as well as learning. A good discussion of these was included in the CCRA2 Cross Cutting Chapter (Street et al., 2016).

### 2.7.2 Task 2b Assess Non-Governmental Adaptation

The next task was to consider additional forms of adaptation that might reduce current and future risks in the absence of further planned Government or other organisational action. It assessed what additional adaptation could happen, including spontaneous and non-Governmental planned adaptation, to help manage risks (or take advantage of opportunities), but also if these non-Governmental responses had the potential for maladaptation.

For some risks or opportunities, there is a strong rationale for non-government action to lead on adaptation, i.e. where an increase in government expenditure would result in a matching decrease in private expenditure, (known as 'crowding out') (HMT, 2018).

In the previous CCRA, the consideration of this type of non-governmental adaptation (e.g. by the private sector or households) was called autonomous adaptation<sup>9</sup>. However, the focus of CCRA3 in step 2 of the method is to establish what could happen in addition to Government planned adaptation. This could include some spontaneous adaptation (i.e. reactive adaptation in response to

<sup>9</sup> The IPCC AR5 glossary (2014b) defined autonomous adaptation as a response to experienced climate and its effects, without planning explicitly or consciously focused on addressing climate change. This is also sometimes called spontaneous adaptation.

the changing climate), which might be termed autonomous. However, it could also include planned non-governmental action, such as planned adaptation by the private sector (including in privatised sectors). By definition, planned pro-active responses cannot be autonomous, irrespective of the actor, because they involve conscious plans and strategies for future climate change. For this reason, the term autonomous adaptation was not used in CCRA3.

Authors were asked instead to assess the potential for reactive, spontaneous adaptation which could arise from direct experience of a changing climate and whether these might manage risks in the absence of, or in addition to government policies and plans. This considered reactive or spontaneous adaptation as for example:

- A natural response, for example, natural species shifts to changing agroclimatic zones, or acclimatisation, for example, the physiological and behavioural acclimatisation of people to experienced higher temperatures.
- An autonomic (unplanned) response in a system, e.g. reduced winter temperatures, leading to reduced winter heating demand in households due to automatic temperature systems, reducing energy demand for heating (noting these can be defined as impact or an adaptation).
- The reactive response of households or the private sector to experienced climate change, including behavioural change (focused on the response to changes experienced, not planned, such as changing behaviour to reduce heat related risks, or fitting household level protection measures), without any Government intervention.
- The reactive market response e.g. changes in demand, etc. as a result of changing prices from experienced climate change.

It also considered planned, proactive adaptation by non-government actors, e.g. planned adaptation to future climate risks by the private sector. There is some information on private sector activities reported under the Climate Change Adaptation Reporting Power (ARP, currently going into its third round, although to note this also includes some governmental organisations as well), though this was not available at the time of CCRA3. The Climate Change Act 2008 allows the Government to ask certain organisations to produce reports on the current and future projected effects of climate change on their organisation and their proposals for adapting to climate change (though the reporting powers were changed from mandatory reporting in the first round to voluntary reporting for the second and current round). At the time of CCRA3, such reports were being prepared by a number of government agencies, authorities and regulators, as well as companies in key privatised sectors (water, energy). As highlighted earlier, this task is also important for opportunities, and the key issue in these cases is to assess whether benefits will be realised without Government action.

The consideration of additional non-Government adaptation (reactive and planned) was used to establish whether risks might be managed - and opportunities realised - even without government intervention. However, there is generally a low evidence base on non-governmental adaptation, and thus this task was primarily qualitative.

When non-Governmental adaptation is present, it is important to consider if it is beneficial, defined through the lens of social welfare, as if not this could be a form of maladaptation. Action by individual actors could, for example, shift vulnerability to others, or could lead to other impacts or disbenefits. As an example, the increase of air conditioning as a response to building overheating is a non-Governmental adaptation response, but it would increase energy use and carbon emissions,

and possibly exacerbate social inequalities (as some can afford to pay for this and some cannot), thus could be a form of maladaptation. Likewise, some farm-level responses (e.g. increased irrigation and fertiliser use) may involve wider cross-sectoral trade-offs that necessitate a role for planned intervention. This assessment also considered cases in which adaptation could have unintended consequences, e.g. creating lock-in, or increasing risks in other sectors or associated with other development or social objectives.

### 2.7.3 Task 2c Analysis of Need for Further Adaptation and Barriers to Adaptation

The final task in Step 2 was:

- To re-assess the magnitude of future risks (or opportunities), with the current and planned adaptation in place, i.e. to identify future residual risk. In general, the output of this task was to identify if risks or opportunities are being managed down to a low magnitude level, though with some exceptions listed below.
- When residual risks remained (magnitude is high, medium or unknown), to assess why action to address these risks (or take advantage of opportunities) was not being taken, i.e. to identify the barriers (constraints) to adaptation.

At the end of this task, there was a re-analysis of the magnitude of future risks or opportunities (from Step 1), taking into account planned adaptation (from 2a) and non-governmental adaptation (from 2b) identified above. This analysis was evidence based and drew on a range of independent sources, including but not limited to the CCC's progress reports, as well as emerging information on the CCC's forthcoming independent assessment of the second Scottish Climate Change Adaptation Programme.

However, in many cases, the assessment of whether current and announced policies or strategies are managing risks often involved a level of expert judgement, especially as there is little academic literature or independent analysis that evaluates the potential effectiveness of Government adaptation policy. To address this, a set of criteria were used to assess whether the risk or opportunity was being managed sufficiently. These are set out in Table 2.7 below.

A risk was only considered to be 'fully managed' if clear plans and objectives were in place, and one of the following is true:

- The planned interventions reduce the magnitude to 'low' across both scenarios of 2°C and 4°C global warming at the end of the century, as defined in Box 2.5, and across the range of uncertainty. The latter was defined in the method as sufficient to manage risks across the probability range, specifically the 10<sup>th</sup> to 90<sup>th</sup> percentiles in the UKCP09 or UKCP18 projections. However, there was rarely the evidence to undertake such an analysis in practice, and authors were asked to consider management of risk across the range of uncertainty as far as possible.
- When a current risk is medium or high magnitude now, and increases further in the future due to climate change, but planned adaptation action will manage this risk (across scenarios of both 2°C and 4°C warming at the end of the century, as defined in Box 2.5, and across the range of

uncertainty) back down to the same absolute levels of risk as today<sup>10</sup>. In this case the risk is considered to be managed provided the future strategies include clear goals and objectives for adaptation, and that the drivers of vulnerability and exposure are being well managed (today and for the future), and there is evidence that this will be delivered with appropriate implementation plans. Furthermore, to be considered fully managed, current risks (and thus residual risks in the future) also needed to demonstrate they had considered recent climate trends including potential unobserved risks today, such as captured through the UNSEEN analysis.

- When a current and future risk is dominated significantly by other factors over and above climate, e.g. as is the case for air pollution, authors were only asked to score the incremental risk from climate change in Step 1. They were then only asked to consider if the risks of additional future climate-related risks were being managed in Step 2.

For opportunities, the analysis considered whether the enabling environment (to take advantage of benefits) was in place, noting at this stage, a low score for an opportunity is a trigger for the consideration of additional action.

In all cases, the justification for this scoring was set out. This assessment (of this adaptation gap) was undertaken for each of the four countries (England, Northern Ireland, Scotland and Wales).

In cases where there was insufficient evidence, but there was widespread agreement between the CCRA authors, CCC and peer reviewers that the risk might not be managed in the future (i.e. an adaptation shortfall), then this triggered further investigation in Step 3. Conversely, if these groups considered that the lack of evidence was not an issue, e.g. because the market was considered to incentivise appropriate action or because Government has commitments in place (with reasons why), then these were not recommended for further consideration and given a “sustain current action” or “watching brief” urgency score.

---

<sup>10</sup> The literature (Burton et al., 2004) identifies that adaptation to future climate will be less effective if adaptation deficits are not first addressed. If there is a medium or high current risk, this could mean there is an adaptation deficit, which could make future adaptation harder. Managing future risks only back down to this current medium or high level will also mean the adaptation deficit continues. However, it is also possible that a trade-off has been made over managing medium or high current risks based on the costs and benefits of further action versus the levels of residual risk, or based on societal risk preferences (see Box 2.7). It is difficult to judge if there is an adaptation deficit today without making a judgement on the risk appetite for addressing risks. The customer requirement from Government excluded the consideration of risk appetite in CCRA3, and thus possible issues around current adaptation deficits have not been considered.

**Table 2.6** Criteria to assess whether risks or opportunities are being managed (in the future).

	<b>Yes (fully)</b>	<b>Partially</b>	<b>No</b>
<b>Risks</b>	<p>Policy, strategy or plan in place, with clear objective (SMART) AND Actions will reduce risk to a low magnitude, across the range of future warming scenarios (2°C and 4°C at end of the century, as defined in Box 2.5, and across the uncertainty range [see text]), OR</p> <p>For risks that already have a medium or high magnitude today, actions are reducing the future risk (in the scenarios of 2°C and 4°C warming at end of the century, and across the uncertainty range) to maintain it at today's level, the drivers of vulnerability and exposure are being well managed (today and in the future), and recent climate trends are well accounted for in the policy, OR</p> <p>For risks that are dominated now and in the future by other factors over and above climate (e.g. air pollution) the incremental risk is being managed down to a low magnitude.</p>	<p>Policy, strategy or plan in place, but no clear objective.</p> <p>Or in place, but only commits to managing risk for 2°C warming pathway, or no uncertainty consideration.</p>	<p>No policy, strategy or plan in place to reduce risk, OR</p> <p>Government action or non-Governmental adaptation is managing risks as set out, but there is a risk of maladaptation, OR</p> <p>Lack of evidence of adaptation, but widespread agreement between the CCRA authors, CCC and peer reviewers that the risk might not be managed in the future.</p>
<b>Opportunities</b>	<p>Opportunity will be fully realised in absence of government intervention OR</p> <p>The enabling environment is in place to fully realise the opportunity.</p>	<p>Opportunity will NOT be fully realised in absence of government intervention and only some elements of the enabling environment are in place.</p>	<p>Opportunity will NOT be fully realised in absence of government intervention and no elements of the enabling environment are in place.</p>
<b>Confidence in the assessment of adaptation (also shown in table 2.4)</b>	<p>High: High quality evidence of the effects of future adaptation in managing the risk and high agreement between experts.</p>	<p>Medium: Some evidence on the effects of future adaptation in managing the risk and/or high agreement between experts.</p>	<p>Low: Little/no/contrasting evidence of the effects of future adaptation in managing the risk and little agreement between experts.</p>

### 2.7.3.1 Barriers

In cases where an adaptation shortfall was identified, the final task was to understand why adaptation is not taking place, i.e. what are the reasons for the adaptation gap. This builds on existing literature that identifies that there are often barriers (constraints) that make it difficult for individuals, businesses and Governments to plan and implement adaptation actions (Cimato and Mullan, 2010; Frontier et al, 2013; Klein et al., 2014). There were two considerations in this barrier analysis:

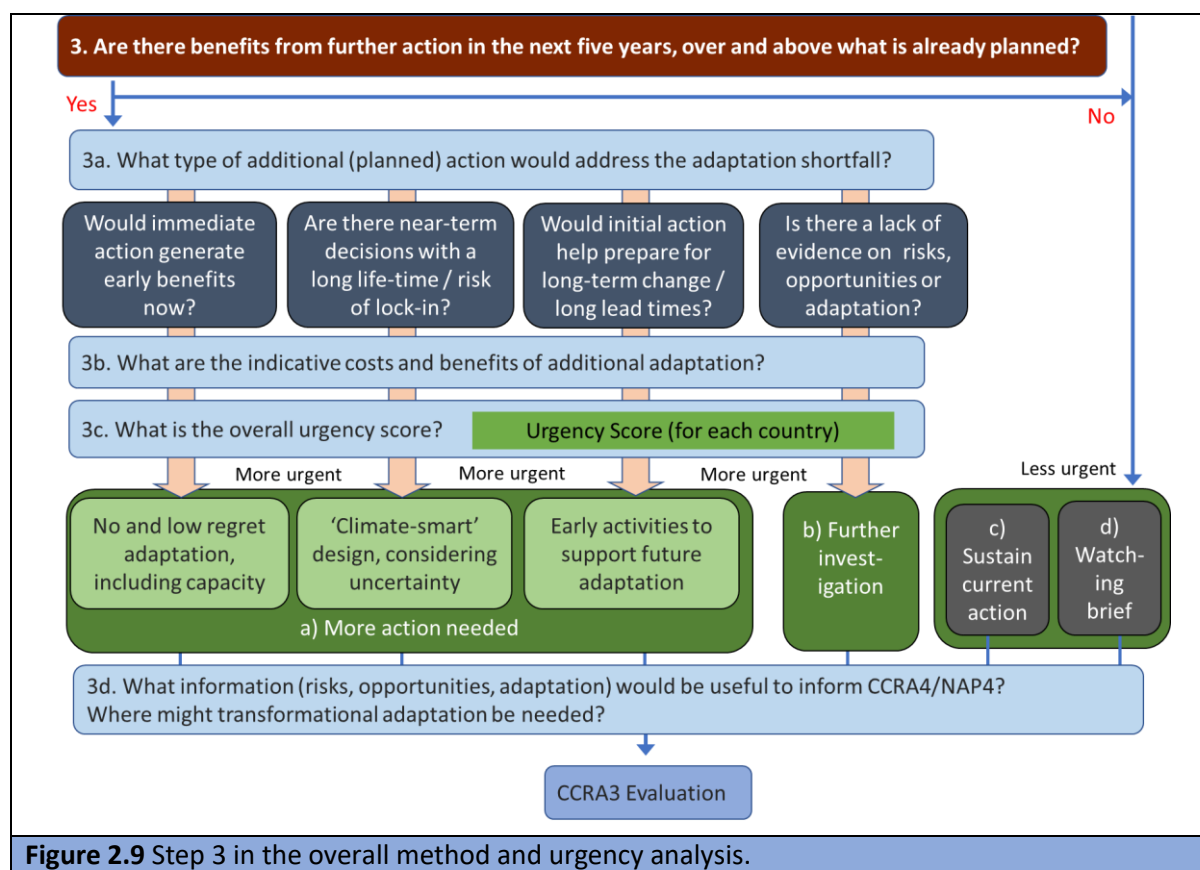

- To identify the barriers that might be stopping or hindering adaptation, e.g. market, information, policy and governance failures, behavioural barriers, etc.
- To assess how these barriers might be overcome, and thus help identify the appropriate type of planned adaptation (linked to Step 3).

These barriers and constraints are also important when considering opportunities. In many cases, the opportunities of climate change may not happen without Government providing the enabling environment, addressing the barriers that allow others to take advantage of the possible benefits.

## 2.8. Step 3 Assess the Benefits of Additional Adaptation Action

In the case where an adaptation shortfall is still identified after Step 2, i.e. the risk is not being fully managed or opportunities are not being fully realised, the final step considers the potential benefits of additional adaptation (see Figure 2.9). The aim is to identify if additional action would be beneficial, over the next five-year period, to manage the residual risks. As outlined above, CCRA3 aims to identify whether future action might be beneficial, but also what type of adaptation might be beneficial, categorised using the three building blocks set out earlier (see Figure 2.3). CCRA3 also has a new focus on understanding the scale, at least at an indicative level, of the potential costs and benefits of further action.

The findings of this analysis – along with other findings from Steps 1 and 2 – are then used to inform the overall urgency score for each risk or opportunity. CCRA3 also included a stronger linkage through to the next CCRA cycle – to CCRA4 – to identify research or information gaps that would help future adaptation (as part of adaptive management).

**Figure 2.9** Step 3 in the overall method and urgency analysis.

Chapter authors were asked to undertake the following activities for risks:

- Identify possible areas of additional adaptation - noting this could be building capacity or creating the enabling environment for adaptation, as well as delivering adaptation.
- Where possible, to suggest the type of additional adaptation that might be relevant, i.e. aligned to the three building blocks (noting that at the national level, it is likely to involve a mix of all three types of intervention). This involves linkages to lock-in risks and thresholds, and also to how adaptation might need to evolve over time considering 2°C and 4°C warming pathways.
- Assess the indicative costs and benefits of further action, as well as possible co-benefits, including synergies (or trade-offs) with mitigation (and Net Zero).
- From the steps above, to identify if further adaptation action would be beneficial.
- For all risks and opportunities (including those identified as low magnitude or being managed): Assign an overall urgency score.
- Identify additional information that would be useful to inform CCRA4/NAP4, both with respect to risks and adaptation.
- For Government/CCC, to start the process for the formal evaluation of CCRA3.

These steps are described in more detail below.

### 2.8.1 Task 3a Analysis of Possible Early Adaptation Options

The first task of Step 3 was to identify potential additional adaptation that could be undertaken to reduce risks or enhance opportunities. This was framed as the additional adaptation scenario. It

considered the broad type of adaptation that could be taken, focusing on the early adaptation priorities set out in Figure 2.3 (i.e. no and low regret options, climate-smart decisions to address lock-in, and early action to inform long-term risks or opportunities), noting that for many risks and opportunities, this may involve a portfolio across all three. In line with the mandate of the CCRA, and the advice from the Government and the DAs (in the Customer Requirement), this did not aim to define the risk appetite, or specifically on how to adapt, since those are policy or operational decisions (and thus fall to the NAP and Adaptation Programmes of the DAs). Instead, the aim was to identify potential additional adaptation interventions that were identified in the evidence and literature, as well as from inputs from chapter experts, stakeholder consultation and the peer review process. This might include direct Government intervention or by creating an enabling environment or building capacity to help others to act.

The focus was to identify additional possible action in the next adaptation reporting period (i.e. the next five years), to address risks in the current, medium or even long-term. A similar approach was taken for opportunities, except for these, it is the potential to seize an opportunity rather than avoid a negative impact that was considered. Authors were asked to consider if there were particular adaptation priorities associated with the risks of lock-in (see section 2.6.3), which would necessitate more urgent action in the next adaptation programme period. Authors were also asked where possible to consider the potential differences in adaptation that would be needed under pathways to 2°C and 4°C global warming, including uncertainty in regional impacts. These can be indicatively identified as part of a pathways approach, especially if there are potential thresholds involved (see section 2.6.3). In some cases, the difference between 2°C and 4°C warming scenarios could be a case of doing more (i.e. with higher sea level rise, there is an incremental increase in coastal protection) but in other cases, it could also mean doing something different (i.e. with higher heat thresholds, a heat alert system may not deliver the necessary adaptation to address health risks and building design may also be needed). Related to this, an important issue here was the rate of change, i.e. as well as how much adaptation action, how quickly this might it be needed. These various elements were introduced to try and encourage a more adaptive management approach, but it is stressed such considerations could only be indicative, given CCRA3 is a synthesis: much greater resources and new analysis are needed to implement adaptive management for each risk and opportunity (as found in the Economics of Climate Resilience study, HMG, 2013; Frontier et al., 2013).

Authors were also asked to consider alternative socioeconomic futures, as these will affect adaptation needs and opportunities, and also allows consideration of different adaptation options, e.g. that tackle vulnerability or adaptive capacity, rather than climate hazards directly.

This task also included a linkage to the Net Zero target, which has important implications for adaptation. CCRA3 authors were asked to consider the synergies and trade-offs between adaptation and mitigation in this task, as part of Net Zero considerations. This followed on from the questions asked in Step 1 (see earlier section) on Net Zero alignment. Authors were asked to consider if additional adaptation action might increase emissions, and thus act to make the Net Zero targets more challenging. This involves a consideration of the changes that will happen along the pathway to Net Zero, i.e. low-carbon electricity generation could reach 75-85% by 2030 (CCC, 2019b) and will be zero carbon by 2050. Conversely, additional adaptation action that had neutral or positive

synergies with mitigation – and especially Net Zero – were considered more relevant (while noting synergistic emissions reductions were not a pre-requisite for further adaptation action).

### 2.8.2 Task 3b Costs and benefits of further action (Indicative)

A new task included in CCRA3, at the request of the Customer Group, was to consider the possible costs and benefits of the further action identified in Task 3a above. As set out earlier, valuation (monetisation) is a standard part of UK government policy development and economic appraisal, as set out in the HM Treasury Green Book (HMT, 2018). It is based on the principles of welfare economics – that is, how the government can improve social welfare or wellbeing. These same concepts are applicable to the identification of possible further adaptation interventions, and the analysis of the benefits of further action. This task involved two economic elements from the Government appraisal process (HMT, 2018).

The first task in the appraisal process is to provide the rationale for intervention. HMT (2018) sets out that a clear rationale for intervention should be identified and then used to develop the objectives or outcomes the government wishes to meet through intervention. The same issues apply when considering further Government action on adaptation (Cimato and Mullan, 2010; HMG, 2013). In CCRA3, the justification for intervention was linked to the barriers identified in Step 2, i.e. the economic, policy and governance barriers that arise from market failures, or information, policy and governance failures. The rationale for intervention considered the relevant barrier or constraints involved with each risk or opportunity, and why adaptation was not already happening. This was then used to provide the economic rationale for early adaptation and some early information on what types of interventions might be appropriate.

The second task in the appraisal process is the consideration of options, starting with a long-list and then undertaking filtering this down to a short-list for detailed economic analysis. (HMT, 2018). The latter involves analysis of the costs or benefits of policies or projects (and options), where possible valued and monetised, in order to provide a common metric. In CCRA3, following from the monetary valuation of risks outlined in Step 1, this task investigated the indicative costs and benefits of the further adaptation action. This information was used to help identify the possible priority areas for action (from Figure 2.3), to assess the possible benefits of further action as compared to costs, and to help inform the urgency score. Given the synthesis nature of CCRA3, this was primarily based on a review of existing evidence and qualitative analysis.

It is stressed that the analysis of the costs and benefits of adaptation is challenging, much more so than for mitigation, and this makes it difficult to gather comparable information on further action across risks and opportunities. For mitigation, benefits are measured using a common burden (tonnes of GHG reduced), irrespective of location and sector, and many studies prioritise options using a cost-effectiveness analysis (£/tCO<sub>2</sub>), which is a relative measure and provides direct comparability across interventions. This also makes it easier to use a synthesis exercise to gather information on benefits of further action. In contrast adaptation benefits require quantification of the reductions in climate impacts (not burdens), and these are time-, sector-, location- and context-specific. Adaptation is also generally introduced as part of a mainstreaming approach in the UK, which requires consideration of multiple metrics, not a single metric, and this means that a cost-effectiveness approach is insufficient. The economic prioritisation of adaptation is therefore better

suited to cost-benefit analysis (CBA). However, because of uncertainty, as well as valuation in non-market sectors and of non-technical options, this normally requires extended cost-benefit analysis or multi-metric appraisal (see Chambwera et al., 2014).

There is also a very low evidence base on the costs and benefits of adaptation and many estimates in the literature are based on technical (engineering) adaptation options for long-term climate change (OECD, 2015). For CCRA3, however, the focus is on the costs and benefits of short-term adaptation priorities (implemented over the next five years), which might have short, medium or long-term benefits. Given the synthesis approach of CCRA3, it was not possible to undertake new analysis, and thus the task drew on previous evidence reviews (ECONADAPT, 2017) and available literature.

It is noted that the consideration of the costs and benefits of adaptation, as part of economic appraisal, does require the use of discount rates, in order to estimate the net present value or benefit to cost ratio. As highlighted earlier, the use of discount rates when calculating the social cost of carbon, or the costs and benefits of mitigation policy, has been very contentious. However, CCRA3 is not looking at mitigation policy: it is focused on domestic adaptation, particularly near-term actions that align within the existing policy decision landscape and thus existing Government recommended discounting approaches. For longer-term adaptation investments, it is stressed that the UK guidance (HMT, 2018) already uses declining discount rates. It is also noted that CCRA3 still prioritises long-term adaptation considerations, see Figure 2.3, with early action to plan for longer-term risks. However, it is highlighted that in future CCRA3s, if transformational adaptation is identified, this may necessitate consideration of intergenerational issues when considering the costs and benefits of further action (and accordingly, the HMT intergenerational discount rate scheme, HMT, 2008).

Towards the end of the CCRA3 process, in late 2020, new HMT supplementary Green Book guidance was published on accounting for the effects of climate change (adaptation) (Defra, 2020). While this was too late to inform this task (3b) in CCRA3, the approach the guidance recommends broadly aligns with the description above.

The consideration of further adaptation also considered if there were additional co-benefits. This included potential synergies (or trade-offs) with mitigation and Net Zero. Previous studies (e.g. Watkiss et al., 2015) have identified that adaptation and mitigation options can lead to synergies and potentially increase the attractiveness of adaptation, though in other cases there is also the potential for conflicts. Finally, as with Task 1a, the potential distribution of costs and benefits associated with adaptation measures was considered, i.e. to consider in broad terms who bears the costs or gains the benefits.

This information was used to assess if further action would be beneficial in managing risks or opportunities. If not, then it was categorised as a 'sustain further action' or 'watching brief'.

### 2.8.3 Task 3c overall urgency score

This task brings together the information above. It addresses the primary goal of the CCRA, which is to provide an assessment of risks and opportunities to inform the priorities for adaptation at the national level, and thus primarily seeks to provide information for the UK Government and devolved administrations.

To do this, an overall urgency score is given to each risk or opportunity. This is undertaken separately for each country. It is stressed that the urgency score provides different information to the magnitude score. For example, even if the future magnitude of a risk is classed as medium in the 2050s, the urgency might be high if plans do not exist to manage this as yet, and might be compounded if there are the risks of lock-in in the short-term. Indeed, for many future risks, there is often a window for intervention (Ballard, Black, and Lonsdale, 2013) today to change the course of action for the future.

In the CCRA context, urgency is defined as a measure of ‘the degree to which action is needed to reduce a risk or realise an opportunity from climate change’. It identifies where the need for adaptation is likely to be most ‘urgent’ between 2023 and 2027 (the next adaptation programme period) and similar periods for the devolved administrations (e.g. for Scotland, the next adaptation programme is due in 2024).

The CCRA3 urgency score follows from the previous three steps, i.e. from the assessment of 1) the current and future level of risk or opportunity, 2) the effects of current and planned adaptation, and 3) the benefits for further beneficial action in the next five years. It assigns a single urgency score for each risk and opportunity for each UK country, along with a summary of what additional adaptation could be beneficial (where relevant) and what this might look like. This simple urgency scoring approach is used because it is transparent and can be understood and considered with ease and speed by policy-makers with responsibility for large and diverse policy areas.

This urgency scoring was used in CCRA2, but some minor changes were made to the approach in CCRA3. It assigns each risk and opportunity one of four urgency scores (see Table 2.8). It is important to note that no risk or opportunity ‘falls out’ of the framework. Risks and opportunities identified as more urgent (‘more action needed’) have a specific and immediate action, but even those identified as less urgent (‘watching brief’ and ‘sustain current action’) require ongoing action and/or monitoring to see if the actions that should be happening, are happening.

Based on the urgency score, the UK Government and devolved administrations then need to decide what specific action to take to address each risk and opportunity. The effectiveness of the National Adaptation Programme for England in reducing these risks and realising opportunities is subsequently evaluated within the CCC’s statutory evaluation role. The CCC has also evaluated the effectiveness of the Scottish Climate Change Adaptation Programme in response to requests from Scottish Government.

**Table 2.7 CCRA3 Urgency Score descriptions.**

<b>Urgency score</b>	<b>Description</b>
<b>‘More action needed’*</b>	<p>New, stronger or different Government action, whether policies, implementation activities, capacity building or enabling environment for adaptation – over and above those already planned – are beneficial in the next five years to reduce climate risks or take advantage of opportunities. This will include different responses according to the nature of the risks and the type of adaptation:</p> <ul style="list-style-type: none"> <li>• Addressing current and near-term risks or opportunities with low and no-regret options (implementing activities or building capacity).</li> <li>• Integrating climate change in near-term decisions with a long life-time or lock-in.</li> <li>• Early adaptation for decisions with long lead-times or where early planning is needed as part of adaptive management.</li> </ul>
<b>‘Further investigation’*</b>	On the basis of available information, it is not known if more action is needed or not. More evidence is urgently needed to fill significant gaps or reduce the uncertainty in the current level of understanding in order to assess the need for additional action.
<b>‘Sustain current action’*</b>	Current or planned levels of activity are appropriate, but continued implementation of these policies or plans is needed to ensure that the risk or opportunity continues to be managed in the future.
<b>‘Watching brief’*</b>	The evidence in these areas should be kept under review, with continuous monitoring of risk levels and adaptation activity (or the potential for opportunities and adaptation) so that further action can be taken if necessary.

\* Note that all risks and opportunities require further research and evidence - not just those listed under further investigation - and all the risks and opportunities in this CCRA require ongoing monitoring (some form of watching brief) on risk / opportunity levels and adaptation activity. The urgency categories assigned are thus the most important priorities.

The four urgency scores have been slightly revised from those used in CCRA2. The category of ‘Research Priority’ in CCRA2 has been replaced with ‘Further investigation’ in CCRA3. This is because of some confusion following CCRA2 that ‘Research Priority’ only denoted that more research was needed, when in fact the urgency is to establish the extent to which further adaptation is required. All risks and opportunities require further research, and given the state of current knowledge, continued research is essential across all the priority risks and opportunities in this CCRA. Similarly, the greater focus on adaptive management recommended in CCRA3 means that all of the priority risks and opportunities should be monitored and measured: it is not just risks or opportunities identified as a watching brief where periodic review and updates are needed. The four urgency scores should therefore be seen as the most important element, but all should be seen as being within a package of ongoing research, monitoring, piloting, evaluation and learning.

It is highlighted that for some risks and opportunities, the lack of quantitative evidence means that expert judgement is needed to assign different risks and opportunities to the urgency categories. To

make this process robust, this was based on the consensus (through consultation and discussion) of Technical Report authors, the CCC, and the CCRA peer reviewers. The information on each risk and opportunity is set out in detail, which accompanies the urgency scores and rationale for those scores, so the reader can see transparently how these were made and can judge the urgency scores for themselves.

CCRA3 does include one additional extension on the urgency score, compared to CCRA2. When the category ‘more action needed’ is identified, then further information is presented on what form that action might take, using the three early adaptation building blocks set out in Figure 2.3, i.e. drawing on information from Task 3a and 3b above. In summary, urgent action is likely to be greater when:

- There is a high short-term adaptation shortfall (i.e. a large current adaptation gap) that provides opportunities for no and low-regret adaptation, and/or
- There is a risk of lock-in from action/inaction in the next five years, and/or
- There are benefits from early action to address major future risks.

## 2.8.4 Task 3d Learning and Evaluation – linking to CCRA4

The final task in CCRA3 is an addition to the CCRA2 method. It seeks to link the successive five-year cycles and encourage adaptive management thinking. Authors were asked where additional information or analysis would be useful to inform CCRA4 and subsequent adaptation programmes. This could be in the form of clearer research priorities, for both risks and adaptation, noting authors were encouraged to prioritise practice orientated research. It could also be in terms of other adaptive management activities, whether monitoring, piloting, learning, building capacity, etc.

Authors were also asked to summarise in a ‘looking forward’ section for each risk or opportunity some key reflections. They were also asked to address the question ‘where might transformational adaptation be needed?’. The rationale for this section was to try and encourage authors to look beyond CCRA3 – to CCRA4 and even later cycles – and identify if adaptation might need to move beyond current incremental activities. In such cases, this may involve a shift from the present-day situation where the aim of adaptation is to maintain the essence and integrity of a current system - to changing the fundamental attributes of a system itself (IPCC, 2014). It is often characterised as moving from ‘doing things differently’ to ‘doing different things’ (see Lonsdale et al., 2015; CRC, 2020). The early consideration of transformational adaptation is important, because by the time of the CCRA4, the UK will be considering actions for the period 2028-2032. If insufficient progress is made globally towards the Paris Agreement during the 2020s, it is likely that the next round of adaptation programmes (NAP4 and the AP of the DAs) will have to significantly scale-up.

Finally, following the publication of the CCRA Evidence and Government Report and the next set of national adaptation programmes, a formal evaluation of CCRA3 should be undertaken prior to CCRA4. This would provide an opportunity to review CCRA3 and introduce a stronger learning element. The results of this evaluation, along with other consultation and stakeholder feedback, should be used in the design of CCRA4. This evaluation would need to be undertaken in 2023, after the CCRA3 Technical Report, Government Report and the National Adaptation Programme.

## Annex 1: Risk/Opportunity template (Round 1)

Templates were used for the first round of the CCRA3 methodology by authors. They were completed for each individual risk and opportunity. For the second round of the methodology, these templates were updated (and are shown below), but rather than using these, authors converted into report sections, as set out in the following chapters.

### Step 1: What is the current and future level of risk/opportunity?

#### **Current risks or opportunities**

Describe current risks or opportunities.

In addition, identify and document additional changes in the current risk or opportunity observed since CCRA1 or CCRA2.

Discuss any observed inequality of the current risks in relation to individual, place and regional dimensions (see note on inequalities description).

#### **Future risks or opportunities**

Describe future risks or opportunities.

Please report evidence that captures low and high scenarios for the mid-century and late century. Ideally this would be for time slices of the 2050s (2040–2070) and 2080s (2070–2100) for scenarios that project global warming to stabilise at  $2^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$  by 2100, or project global warming to reach  $4^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$  in 2081 – 2100. If information is not available for these time slices in projections of those rates of global warming, it may be appropriate to examine projected climate changes at global warming levels of  $2^{\circ}\text{C}$  and  $4^{\circ}\text{C}$  reached at other times, and apply these to the required dates. The validity of this will depend on whether the specific climate variables being assessed have a strong dependency on the rate of warming rather than its instantaneous magnitude, and needs to be judged on a case-by-case basis. In addition:

- Report the scenario and the time period for the evidence cited. When evidence relates to standard time slices, please document scenario and time period (e.g. RCP2.6, 2071-2100, relative to baseline period 1971-2000). When evidence is for global warming levels please document the GWL and time period (e.g.  $2^{\circ}\text{C}$  GWL, relative to preindustrial, exceeded in time period centred on 2070).
- Document the uncertainty. This should report the scenario uncertainty associated with the evidence (e.g. RCP2.6, SRES A1B, etc) and the climate model uncertainty for each scenario (e.g. 10<sup>th</sup> to 90<sup>th</sup> percentile range from UKCP09).
- Document the relative importance (where evidence exists) of the climate change versus the socio-economic drivers in the evidence reported.

Please capture and report on any tail-end risks, including low-probability high-consequence extremes (events). This could be High++ studies, or projected changes with rates of warming above the 50<sup>th</sup> percentile of probabilistic projections with the RCP8.5 emissions scenario. It may help to consider the question '*how bad could things plausibly get?*'

Discuss projected changes in risks or opportunities across affected populations, across the individual, place and regional dimensions (see note on inequalities description).

Use this information to score the magnitude (see final section).

Lock-in	Identification of potential lock-in risks, or loss of opportunities, focused on next reporting period (current, 2022 – 2027). <i>Could these affect the urgency score (link to Step 3)?</i>																														
Thresholds	Document thresholds, whether biophysical thresholds, engineering, performance or policy thresholds. Does exceedance of these vary over scenarios or across projections (uncertainty)? Please consider results of the CCRA3 Thresholds research project. <i>Could these alter the magnitude score (expert judgement and agreement across authors)?</i>																														
Interacting risks	Document interacting risks and potential size. Please consider results of the CCRA3 Interacting Risks research project. <i>Could these potentially increase the magnitude score?</i>																														
Net Zero	1) Is the net zero target likely to increase or decrease the magnitude of the risk/opportunity? 2) Could the climate change risk or opportunity make the net zero target easier or harder to achieve? (See net zero supplementary note)																														
Overall magnitude and evidence	<p>Score the magnitude using the magnitude tables, with the differentiated scoring matrix <u>for each country</u>. Report on the quality of evidence (see magnitude tables and quality of evidence table supplementary note).</p> <p><u>Score Current Magnitude</u></p> <table><tr><td></td><td>England</td><td>NI</td><td>Scotland</td><td>Wales</td></tr><tr><td><b>Magnitude</b></td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td></tr><tr><td>Quality of evidence</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td></tr></table> <p><u>Score Future Magnitude</u></p> <p>Note that the future magnitude score is based on the highest risk or opportunity score across all scenarios and time periods, including consideration of available information on uncertainty ranges (but not including tail end risks).</p> <table><tr><td></td><td>England</td><td>NI</td><td>Scotland</td><td>Wales</td></tr><tr><td><b>Magnitude</b></td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td><td>H /M /L /Unknown</td></tr><tr><td>Quality of evidence</td><td>H /M /L</td><td>H /M /L</td><td>H /M /L</td><td>H /M /L</td></tr></table> <p><i>If the risk or opportunity scores as a medium, high or unknown for current or future, progress to Step 2.</i> <i>If it scores low in both current and future, go to Step 3.</i></p>		England	NI	Scotland	Wales	<b>Magnitude</b>	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	Quality of evidence	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown		England	NI	Scotland	Wales	<b>Magnitude</b>	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	Quality of evidence	H /M /L	H /M /L	H /M /L	H /M /L
	England	NI	Scotland	Wales																											
<b>Magnitude</b>	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown																											
Quality of evidence	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown																											
	England	NI	Scotland	Wales																											
<b>Magnitude</b>	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown	H /M /L /Unknown																											
Quality of evidence	H /M /L	H /M /L	H /M /L	H /M /L																											

**Step 2: Is the risk/opportunity going to be being managed, taking into account government commitments and other adaptation?**

Describe current and announced planned adaptation (including adaptive capacity).

*Who is responsible for adaptation (institutional landscape)?*

*What plans are in place or published?*

Document the changes in adaptation, and potential benefits from current adaptation, that have occurred since CCRA1/CCRA2.

*What effect adaptation actions have had on the level of current risks between 2012 and now?*

Document the potential reduction in future risks / realisation of future opportunity from the planned adaptation in place. This should also consider if government action involves potential maladaptation, or involves lock-in.

For opportunities, the steps are slightly different. There is a need to consider spontaneous and non-government planned adaptation first, and then to assess whether these actions are likely to be sufficient to fully realise potential benefits or whether there is an additional need for Government action, and if so, whether this is in place.

Is there an adaptation shortfall in planned adaptation?

Based on the analysis above, assess if there is a shortfall.

Yes/No/Unknown

To score yes, risks should be managed across the uncertainty range (but not including tail end risks).

Evidence

Document the evidence.

Quality of evidence

Rate the quality of Evidence – high, medium, low.

(see magnitude tables and quality of evidence table supplementary note – quality of evidence row 2).

Will this shortfall be addressed by non-governmental adaptation?

Will other forms of adaptation, including action by the private sector or households, reduce the risks / realise opportunities, in the absence of planned government action? Yes/No

Evidence

Document the evidence on non-governmental adaptation.

What are the barriers to adaptation?

If there is an adaptation shortfall, discuss the barriers or constraints that stop adaptation being managed .

Is the risk being managed or is there an adaptation shortfall?

Re-score the magnitude from Step 1 with information above.

Future Magnitude with existing adaptation action

	England	NI	Scotland	Wales
<b>Magnitude</b>	H /M /L/ Unknown	H /M /L/ Unknown	H /M /L/ Unknown	H /M /L/ Unknown

*If there is still a medium or high or unknown magnitude, progress to Step 3. If there is a low risk (no adaptation shortfall) with planned and other action, then go to urgency score (Sustain current action / Watching brief).*

**Step 3: Are there benefits to further action in the next five years, over and above what is already planned?**

Describe potential additional adaptation that could be taken.  
Document the evidence on possible additional actions.

This can describe possible additional adaptation, but should not be prescriptive on new policy. Ideally, please try and capture the type of early adaptation (that could be introduced in the next five-year period) and how it aligns to the 3 building blocks and linkages, i.e.:

- i) Low or no-regret adaptation (including capacity building).
- ii) Climate-smart' design or mainstreaming in early decisions.
- iii) Early adaptation activities to support future decisions and action or a combination (portfolio) of all of these.

For opportunities, this should consider additional adaptation to fully realise potential benefits (including creating the enabling environment).

What might be the additional costs and benefits of further adaptation?

Describe any observed and projected implications for distribution of adaptation (i.e. will the strategy benefit some groups/areas more than others, and/or leave others at a disadvantage?)

Are there synergies or trade-offs with mitigation and the net zero target? Does this affect the attractiveness of different types of further action?

Are there benefits of action in next 5 years?	Based on the analysis above, are there benefits of further action? Yes/No
---	--

Urgency ranking	Score urgency (into one of four scores):
-----------------	--

- More action needed.
- Further investigation.
- Sustain current action.
- Watching brief.

	England	NI	Scotland	Wales
<b>Urgency score</b>				

	Document the rationale for urgency ranking.
--	---

Confidence	Rate the quality of Evidence – high, medium, low. (see magnitude tables and quality of evidence table supplementary note – quality of evidence row 3).
------------	---

CCRA4 and transformational adaptation	What information (risks, opportunities, adaptation) would be useful to inform CCRA4/NAP4? Where might transformational adaptation be needed?
---------------------------------------	---

UK Climate Risk  
Independent  
Assessment (CCRA3)

# Technical Report

## Chapter 3: Natural Environment and Assets

Lead Authors: Pam Berry, Iain Brown

---

**Contributing Authors:** Richard Betts, Pete Falloon, Debbie Hemming, Mike Morecroft, Stephen Thackeray, Kairsty Topp, Paul Watkiss

**Additional Contributors:** Brendan Freeman, Kathryn Brown, Amy Bell, Jade Berman, Alistair Hunt, Jane McCullough, Alan Netherwood, Catherine Payne, Rob Knowles

**This chapter should be cited as:**

## Key messages

A healthy, functioning natural environment is important not just for biodiversity, but also for the continued provision of key ecosystem services to the economy and to the health and well-being of our society. This chapter assesses individual risks and opportunities posed by climate change to the natural environment, whilst recognising the need to view them also from a systemic perspective.

- **More action is still needed on many risks, as the current and future projected impacts of climate change and adaptation responses are inadequate to match the scale of the risk or to realise potential opportunities** (Table 3.1). Risks previously identified as “More Action Needed” in CCRA2 include: risks to terrestrial species and habitats (section 3.3); risk to soils (section 3.6), risks to natural carbon stores and sequestration (section 3.7) and risks and opportunities to coastal species and habitats (section 3.19).
- **More action is needed if the risks and opportunities for agricultural and forestry productivity from new/alternative species are to be addressed (section 3.11).** This risk has changed from a “research priority” to “more action needed” due to increased availability of evidence on the magnitude of the risk, and the very significant adaptation shortfall, including the significant lead time to develop and implement actions in the land use sector.
- **More action is needed on the risks to freshwater species and habitats (section 3.13) and marine species, habitats and fisheries (section 3.16).** Both these risks have changed from being a “research priority” in CCRA2 due to an increasing amount of evidence on specific impacts, which suggests that the risks are already increasing and are a very likely to increase further, whilst current adaptation currently is insufficient.
- **New evidence of the potential impacts of climate change suggests risks to the natural environment from pests, pathogens and invasive non-native species (INNS) are high or increasing.** These risks relate to terrestrial (section 3.4) and freshwater (section 3.14) species and habitats, agriculture (section 3.9) and forestry (section 3.10), and to marine environments (section 3.18). These have all changed from “sustain current action” to “more action needed”, as there is increasing evidence of rising temperatures increasing the spread of pests and pathogens, with trade increasing the possibility of the arrival and establishment of INNS. The new risk descriptor Risks to marine species and habitats from pests, pathogens and invasive species (section 3.18) also concludes that there is an urgent need for “more action” to improve preparedness and address some of the key uncertainties.
- **More research is needed to improve knowledge about and awareness of the opportunities from climate change if they are to be fully realised, thus the opportunities are mostly assessed as needing “further investigation”.** These opportunities cover new species colonisations in terrestrial habitats (section 3.5), agricultural and forestry productivity from new/alternative species becoming suitable (section 3.11) and for marine species, habitats and fisheries (section 3.17). There is also a need to build adaptive capacity and to trial ways for opportunities to be fulfilled without creating risks for other species, so

that appropriate action can be taken. Opportunities for freshwater species and habitats (section 3.15) are assessed as “sustain current action”, as many of the opportunities do not directly come from climate change, but from human activities/trade. The realisation of each opportunity is closely related to the adaptation actions taken in their associated risk.

- **Risks to aquifers and agricultural land from saltwater intrusion (section 3.12) remain low.** The urgency score has changed from “sustain current action” to “further investigation” (England and Wales), as there is scope for some additional research to check assumptions on exposure and sensitivity. For Scotland and Northern Ireland, where there is a lower risk in the scale of exposure, a continued “watching brief” is more appropriate.
- **Risks and opportunities to landscape character (section 3.20)** has changed from a watching brief to further investigation of how adaptation could be effectively integrated with landscape concepts and to encourage support for the testing of policy for and implementation of such an approach.
- **Many of the risks and opportunities in the natural environment interact with the evolving Net Zero greenhouse gas emissions agenda.** Some potential synergies with adaptation actions have been identified, especially for woodland creation and peatland restoration, low carbon farming, and wetland and coastal/marine habitat and saltmarsh restoration. However, there are additional risks if adaptation, biodiversity and other factors related to wider ecosystem services are not given sufficient weight in decision making about mitigation. Good spatial targeting of the right measure in the right place is also critical and this will need to be more cognisant of the implications of a changing climate. A large increase in the area devoted to bioenergy production could present considerable risks to adaptation, biodiversity and sustainable food production, and research is needed to avoid these.
- **More integrated ecosystem-based approaches or nature-based solutions can contribute to adaptation in the natural environment and in other sectors.** This is due to the high-level of inter-relationships within the natural environment and with other sectors through the ecosystem services that it provides, including to infrastructure, people and the built environment, and businesses. Currently, implementation of these approaches in the context of climate change is limited and is not always integrated with adaptation in such a way as to realise synergies and minimise trade-offs or unintended consequences. Nevertheless, they provide a promising way forward for a more integrated and more effective adaptation that works with, rather than against, the resilience of the natural environment.
- **The risks and opportunities are assessed as increasing from now to the 2050s and the 2080s, and for 4°C global warming by 2100 compared to 2°C.** However, the limited amount of new evidence available for some risk descriptors made it difficult to assess the risk magnitude, especially across the different countries. This was compounded by a lack of clear evidence of the effectiveness of many adaptation actions, which may be related to the time taken for many of them to become effective in reducing the risk, but also because this

requires a much greater investment in systematic monitoring of indicators of vulnerability and exposure than is generally occurring at present.

**Table 3:1.** Urgency scores for risks and opportunities to the Natural Environment and Assets

Risk number	Risk / Opportunity description	Urgency scores			
		England	Northern Ireland	Scotland	Wales
N1	Risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N2	Risks to terrestrial species and habitats from pests, pathogens and invasive species	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N3	Opportunities from new species colonisations in terrestrial habitats	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further Investigation  (Low confidence)	Further investigation  (Low confidence)
N4	Risks to soils from changing climatic conditions, including seasonal aridity and wetness.	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)

N5	Risks and opportunities for natural carbon stores, carbon sequestration and GHG emissions from changing climatic conditions, including temperature change and water scarcity	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)
N6	Risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind and saline intrusion).	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N7	Risks to agriculture from pests, pathogens and invasive species	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N8	Risks to forestry from pests, pathogens and invasive species	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N9	Opportunities for agricultural and forestry productivity from new/alternative species becoming suitable.	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Low confidence)
N10	Risks to aquifers and agricultural land from sea level rise, saltwater intrusion	Further investigation  (Medium/low confidence)	Watching brief  (Low confidence)	Watching Brief  (Low confidence)	Further investigation  (Medium/low confidence)

N11	Risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts.	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N12	Risks to freshwater species and habitats from pests, pathogens and invasive species	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N13	Opportunities to freshwater species and habitats from new species colonisations	Sustain current action  (Low confidence)	Sustain current action  (Low confidence)	Sustain current action  (Low confidence)	Sustain current action  (Low confidence)
N14	Risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures.	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)	More action needed  (Medium confidence)
N15	Opportunities to marine species, habitats and fisheries from changing climatic conditions	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Low confidence)
N16	Risks to marine species and habitats from pests, pathogens and invasive species	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)	More action needed  (Low confidence)

N17	Risks and opportunities to coastal species and habitats due to coastal flooding, erosion and climate factors	More action needed  (Medium confidence)	More action needed  (Low confidence)	More action needed  (medium/low confidence)	More action needed  (Medium confidence)
N18	Risks and opportunities from climate change to landscape character	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Low confidence)	Further investigation  (Medium/low confidence)

### 3.1 Introduction

Climate change continues to affect the natural environment across the UK and so this chapter has the same general scope as of Chapter 3 in CCRA2, and correspondingly recognises the key principles of the ecosystem approach, including the interdependencies and benefits of the natural environment for the economy and broader society/human well-being, including the arts and cultural services. Nevertheless, CCRA3 has adopted a different framing of risks compared to CCRA2. Therefore, following stakeholder engagement, risks descriptors are defined based upon significant policy issues to facilitate a closer assessment of evidence in the context of policy actions. This also includes a wider inclusion of prospective opportunities as an additional component of climate change adaptation. The separation of opportunities from risks enables the potential benefits of climate change to be recognised, as well as helping refine the scoring, such that the two are not conflated. The natural environment chapter, therefore, examines the evidence of climate change organised across 18 key risks and opportunities for terrestrial, freshwater, coastal and marine natural environments, as well as for agriculture and forestry and the landscape.

The natural environment constitutes our natural capital, which directly or indirectly produces goods and services for people. It underpins provisioning services, such as agriculture and forestry, as well as water, air and soil regulation, whilst also providing opportunities for recreation and the enjoyment of wildlife and landscapes. In order to leave the environment in a better state for future generations it has been suggested that we need a transformational approach which includes a review of how we view our natural capital and measure economic success, especially for a sustainable future (Dasgupta, 2021). This natural capital is often discussed in terms of capital assets and forms part of the guidance on the risk magnitude scoring (Chapter 2: Watkiss and Betts, 2021). So, another consideration when organising the risks was to align them more closely with a natural capital approach. That is, the risks to and opportunities of climate change for terrestrial, freshwater, coastal and marine natural environments, habitats and species representing natural assets, with the others representing ecosystem services (e.g., N5 Risks to natural carbon stores, carbon

sequestration and greenhouse gas (GHG) emissions - regulating services, N6 Risks to and opportunities for agricultural and forestry productivity - provisioning services, N18. Risks and opportunities from climate change to landscape character – cultural services). This chapter examines the evidence regarding the key risks and opportunities of climate change to each of these, whilst other selected regulating services (urban cooling, pollination, water quality and soil regulation) are covered under the relevant risk.

### 3.1.1 Context and scope of chapter

There is a variable, but increasing, amount of evidence available for the assessment of the magnitude of each risk descriptor, as the chapter is based on new evidence since CCRA2, although there is less available for the opportunities. The amount available has, to a large extent, been dependent on the interest of particular risks to policy and decision makers and to the research community. As far as possible, the risks and opportunities are assessed separately for England, Northern Ireland, Scotland and Wales, as there are geographical differences in climate impacts, as well as policy contexts. However, political boundaries are not a usual unit of analysis for the natural environment, with evidence being associated with habitats, catchments, geology or soil types and so on, thus it was not possible to report on the current and future climate impacts by country. Many of the adaptation actions taken in one country are relevant to other parts of the UK, but thus far this has not been considered when assessing the risk, unless there is specific mention of such actions being applied. One constraint for the natural environment is that, while often there is a range of adaptation actions that have been proposed or undertaken, it often takes (a long) time for these actions (e.g., tree planting) to produce an effect. Also, we currently lack robust metrics/indicators and long-term monitoring to measure the effectiveness of actions for many risks and opportunities. Thus, even if appropriate long-term monitoring is in place, adaptation has not yet had a measurable effect on reducing the magnitude of the risk. In addition, while there are a range of climate change adaptation actions proposed for habitats and species, it is often very difficult to assess their effectiveness due to the complexity of response of natural systems and the fact that they are responding to various other environmental and socio-economic pressures, of which climate change is only one. Even then, climate change can exacerbate the impacts of other pressures, as is the case with wildfire (Box 3.1) which is an important cross-cutting risk that originates in the natural environment and has a distinctive climate sensitivity and changing pattern of exposure. Consistent with the ecosystem approach, we recognise that the natural environment is fundamentally interconnected and, therefore, managing individual risks (or opportunities) in isolation can have major secondary effects for other risks (both positive and negative). Thus, for CCRA3, an additional objective has been to develop a more systemic approach to highlight these inter-relationships, including to other CCRA chapters. Interacting and cross-cutting risks are considered in more detail at the end of the chapter (Sections 3.21.2 and 3.21.3). Identifying interactions has been facilitated by the Interacting Risks supporting project, which assessed interacting and cascading risks within and between the natural environment, the built environment and infrastructure (WSP *et al.* 2020). They found that the natural environment was the most frequent recipient of risk flows from other impacts. However, it is important to realise that these interactions mean that the natural environment also can contribute to adaptation across risks and in other sectors, for example through the use of nature-based solutions.

### Box 3.1: Wildfire Risk

- Wildfire occurrence is episodic with events linked to the occurrence of dry or hot weather and fuel availability from vegetation, plant litter and soil organic matter.
- A wildfire 'season' with distinct peaks in spring and summer can be recognised from event data (Belcher *et al.*, 2021).
- The vast majority of wildfires in the UK are a result of human agency (deliberate or accidental) rather than from lightning strikes.
- Analysing current trends in annual wildfire occurrence is difficult due to limited long-term data (standardised incidence reporting only occurred since 2008 and can still be of variable quality) and their episodic frequency which means considerable interannual and multi-year variability (Davies and Legg, 2016; Belcher *et al.*, 2021; Costa *et al.*, 2020; Glaves *et al.*, 2020). Analysis to update the CCC Adaptation Indicators (ADAS, 2019) in England reported that for 2009-2017, 130,370 wildfire incidents were recorded, burning an area of 35,557ha. Mountain heath and bog made up around half of this area, with improved and semi-natural grassland and arable land making up a further 40%. It found a strong correlation between wildfire incidence and drought conditions, consistent with reports of spikes in wildfires during such periods. For example, sustained dry weather in July 2018 in Northern Ireland required the Fire and Rescue Service to attend an unprecedented number of gorse fires (1,061; a 1053% increase on the same period in 2017).
- Despite these data challenges, there is some evidence for an increase in wildfire size and severity in recent years, and indications for an earlier start to the wildfire season (Belcher *et al.*, 2021).
- Analysis has suggested that the use of the same threshold values throughout the UK underestimates wildfire danger in the cooler parts of the UK, hence more recent work has used variable thresholds based upon percentiles (De Jong *et al.*, 2016).
- Wildfire climate modelling uses a concept of wildfire danger to characterise meteorological risk factors and to distinguish them from other trigger factors associated with ignition (fuel load, human agency etc.). The combination of these factors defines wildfire risk.
- Future modelling using climate change projections (UKCP18 or CMIP5) suggests a significant increase in summer wildfire danger but only a slight increase in spring (Belcher *et al.*, 2021; Perry and Vanvy, 2021; Arnell *et al.*, 2021).
- Future modelling also indicates that the highest risk areas will be in south/east England but that the change in risk may be most pronounced for UK locations in the north and west that currently have a rather lower present-day risk (Perry and Vanvy, 2021 Arnell *et al.*, 2021).
- Headline indicators of fire danger based upon threshold exceedances vary depending on indicator, but average number of danger days increases 3-4 times by the 2080s (compared to a 1981-2010 baseline) (Arnell *et al.*, 2021). In addition to changes in temperature and rainfall patterns, reductions in relative humidity have an important influence.
- In addition to severe consequences for the natural environment (see Risks N1, N4, N5, N6, N18), wildfire can also have notable detrimental effects for the built environment and human health (Chapter 5: Kovats and Brisley, 2021), also including impacts on transport infrastructure (Chapter 4: Jaroszweski, Wood and Chapman, 2021), and businesses (Chapter 6: Surminksi,

2021) (Belcher *et al.*, 2021). There are also notable cross-sectoral risk interactions which can occur through wildfire events (see Figure 3.1).

- Responsibilities and governance of wildfire risk is rather variable across the UK and in different regions, including lack of clarity on lead organisations for co-ordinating adaptation actions and overall strategy. There is often limited evidence that awareness of changing risk has been incorporated into risk management, including a tendency towards a reactive rather than proactive approach, which can constrain adaptive capacity (Gazzard *et al.*, 2016; Moffatt and Gazzard, 2019).
- Prescribed burning of moorland has for a long time been used as a traditional management practice. Important differences regarding biodiversity and ecosystem services can occur due to differences in intensity between shallow and deeper burns and on diverse habitats (including peatland), which highlight the importance of good practice (Belcher *et al.*, 2021). With regard to risk reduction, it is therefore crucial that good practice is further adapted to be consistent with the changing risk from climate change, as informed by further research and knowledge exchange.
- The Fire and Rescue Service's (FRS) Integrated Risk Management Plans (IRMPs) and local strategies need further development to include climate change.
- An improved system for fire danger and other risk factors, specific to UK conditions, would enhance risk assessment, including use in scenario planning.
- Regional and national wildfire forums can have an important role in improving awareness through knowledge exchange on changing risk magnitudes, good practice, and cross-sectoral initiatives, although their role is advisory (Gazzard *et al.*, 2016).
- There are important interactions between the Net Zero agenda and changing climate risks for wildfire which are yet to be fully assessed and included in planning strategies.
- Wildfire risk is included in the National Security Risk Assessment (NSRA), but this requires further consideration of how climate change is incorporated in risk profiling, including links to the CCRA, consistent with planning for a reasonable worst-case scenario (UK Parliament POST, 2019). In addition, there is concern that the NSRA does not fully consider impacts on the natural environment, including loss of ecosystem services.

CCRA3 follows on from the publication of UKCP18 climate scenarios and associated studies (see Chapter 1: Slingo, 2021), and the further insights these provide are highlighted where possible. However, relationships between the natural environment and climate data are typically complex, and in some instances difficult to generalise especially when based upon limited examples, therefore advances based upon UKCP18 remain work in progress. Thus, for many risks, they may confirm our confidence in direction of travel, but without further evidence we have low confidence in the outcomes in quantitative terms. The natural environment is not just affected by changes in mean annual or seasonal climate parameters, but also by more extreme events. CCRA3 has sought to identify these Low Likelihood High Impact events and their possible consequences (Box 3.2).

### Box 3.2: Low Likelihood High Impact (LLHI) Events

The natural environment is also exposed to infrequent high magnitude events that occur at the extremes of climate change projections (see Chapter 1: Slingo, 2021). Some links have already been suggested between extreme climatic events and population crashes and explosions for birds and Lepidoptera in England (Palmer *et al.*, 2017). Even small changes in frequency or magnitude may have profound implications for resilience and adaptation planning. These events can be

especially damaging because of the occurrence of thresholds and tipping points in natural systems and their myriad interconnections, beyond which systems reorganise around different connections and properties that also affect ecosystem services provided to humans (see section 3.20.3). Four distinctive examples are highlighted to demonstrate the importance of LLHI events.

Firstly, and quite probably the most severe risk to the natural environment as a whole, would be from the occurrence of a severe and sustained drought occurring over a large part of the UK. In synoptic terms, this is typically associated with an extended phase of anticyclonic ‘blocking’ that acts to exclude sources of rainfall for a considerable duration, or even for multiple phases of blocking across consecutive seasons as occurs when a dry summer follows a dry winter. The latter situation can act to deplete groundwater reserves that require winter rainfall for recharge, hence both surface and groundwater reserves become severely depleted during summer (and even into autumn). In addition, very high soil moisture deficits and resultant feedbacks through reduced evapotranspiration can further exacerbate and perpetuate drought severity. Analysis of UKCP18 shows that, despite ongoing uncertainties regarding drought prediction, the possibility of this scenario is increasing (Chapter 1: Slingo, 2021) and that enhanced soil moisture droughts are a specific high-risk category.

The consequences for biodiversity (terrestrial and freshwater) and for agriculture and forestry from such an event scenario would be very severe, but possibly further compounded by cross-sectoral conflicts over water availability because such a scenario would challenge existing procedures and plans (e.g., ‘drought orders’) and would involve the interaction of multiple CCRA3 risks together. In addition, such a situation may potentially lead to a significantly increased risk of large-scale wildfires for which contingency planning appears to be limited.

Secondly, agriculture, and especially intensive arable cropping and horticulture, is particularly vulnerable to combined negative effects of anomalous seasonal variations. As discussed for Risk N6, an unprecedented and unforeseen catastrophic wheat harvest occurred in the ‘breadbasket’ regions of France in 2016 due to the unusual combination of an anomalously warm autumn followed by a wet spring, conditions which are also projected to increase in future (Ben-Ari *et al.*, 2018). As recent years have shown, the UK is also vulnerable to poor harvests: reductions in yields reduced the export value of wheat by 73% and 84% in 2017 and 2018, respectively, and increased the import expenditure by 38% and 79% (DEFRA, 2019a); in addition, wheat production in 2020 was down 40% on 2019 values, primarily due to the previous wet autumn/winter. Much of the UK’s current arable and horticultural land area is in east and south-east of England but recent joint probability analysis of the spatial coincidence of combined hot, dry and wet extreme events has shown that this region is most exposed to the likelihood of such combined events over recent decades (joint probability values of 0.69 to 0.99: Dodd *et al.*, 2020), although further work is required to assess risk for a specific growing season.

With projected trends towards an increased likelihood of wetter winters and hotter drier summers (UKCP18 and other projections), there is an increased joint probability of a scenario arising where negative impacts from consecutive bad seasons accrue and are compounded throughout the crop growing period, resulting in major losses in crop production. In such a situation, the UK becomes more reliant on overseas imports but if large-scale atmospheric

teleconnections also mean that other important agricultural production areas are also negatively affected at the same time, then there may be potential consequences for food security (see Chapter 7: Challinor and Benton, 2021). These challenges for agriculture are further exacerbated because the UK population is increasing and therefore more food will be required to feed the country (notwithstanding potential diet changes, food waste reduction etc.).

Thirdly, the prevalence of sustained storm conditions throughout a season or longer period can have severe consequences for coastal environments as noted in Risk N17. This is typically associated with a vigorous westerly (zonal) circulation, typically associated with a positive North Atlantic Oscillation during the winter months or a longer period. For example, the winter season of 2013/2014 was the stormiest on record for the British Isles (Priestley *et al.*, 2017) with an unprecedented amount of cyclone clustering corresponding to an average of one intense cyclone affecting the country every 2.5 days. These persistent cyclonic conditions were associated with a strong and straight upper-level jet stream flanked by Rossby wave features breaking on both its northern and southern sides for the duration of the clustering event. For the coastal environment, continued presence of storm conditions in winter 2013/14 with large amounts of wave energy caused major erosion and flooding, which then takes many years for habitats and species to recover from. With the increased likelihood of such severe winter cyclonic conditions increasing in future projections provided by UKCP18 (Chapter 1: Slingo, 2021), in combination with higher water levels from ongoing sea-level rise, there is the increased prospect of passing a threshold where existing coastal systems are unable to recover and reconfiguration of vulnerable habitats and ecosystems occurs, with both loss of areas of high biodiversity value and loss of coastal ecosystem services (Section 3.21.3) (see also Chapter 4: Jaroszweski, Wood and Chapman, 2021). These implications also extend to the marine environment, where shallow-water habitats such as seagrass beds and serpulid reefs are vulnerable to an increased pattern of storm frequency that over-rides their natural recovery time between time events (section 3.16.1).

A fourth example can be identified with particular importance to the marine environment due to expected changes in ocean circulation. The Atlantic Meridional Overturning Circulation (AMOC) transports large amounts of sub-tropical water into the higher latitudes of the North Atlantic. Although AMOC exhibits considerable variability, future projections indicate sustained slowdown as downwelling zones in the Arctic that drive the circulation become fresher and also due to changes in the tropics (Liu *et al.*, 2020). This large-scale circulation is intricately linked to other ocean currents that have a strong influence on the temperature and salinity of the seas around the UK, with major implications for the future of marine ecosystems (McCarthy *et al.*, 2020). Most notably at higher magnitudes of climate change, this also increases the likelihood of increased instability and volatility in AMOC, although the dominant atmospheric effect will continue to be a strong warming trend (as shown by UKCP18 and other projections). While a complete shutdown of the AMOC and associated severe cooling of NW Europe (as occurred at the transition from the last glaciation) is considered very unlikely this century, it remains a plausible outcome in the next century (Chapter 1: Slingo, 2021). Nevertheless, significant weakening of the AMOC is considered likely and the latest generation of models project stronger weakening than previously projected, with a possible AMOC decline between 34% and 45% by 2100.

Similarly, further utilisation of future socioeconomic scenarios (for example, based upon the IPCC SSP framework) are at an early stage. Much of this chapter, therefore, is based on studies using UKCP09 or IPCC climate scenarios and relatively few apply socioeconomic scenarios. Thus, it has not been possible to determine the contribution of climate versus socio-economic drivers on the magnitude of the risk or opportunity.

Social and economic trends also are relevant to the future risks from climate change and can influence future magnitude through changes in exposure and vulnerability (see Chapter 2: Watkiss and Betts, 2021). A new consistent set of UK socio-economic projections has been produced for CCRA3 (Cambridge Econometrics, 2019) which include projections of land-use, land use change and forestry activities in the future, “taking into account current land use policies and/or aspirations (e.g., achieving a certain percentage of forest cover by 2050)”. The central projection assumes current policies and funding, non-forest rates and 2014 afforestation planting rates continue at the same rate into the future, although this planting rate is very low (e.g., for Scotland and does not reflect current policy/practice). These projections do include a high scenario, which assumes ambitious levels for afforestation, and full restoration of peatlands. Since these projections were produced, the UK has adopted a Net Zero target (see below). However, there is comparatively little evidence available on the implications of the Net Zero target for some risks, although it is more relevant for those related to agriculture and forestry.

Socio-economic factors also can influence adaptation, in terms of the capacity to act, but again there is generally a lack of evidence on the amount they can contribute. They can also affect the adaptation options considered and implemented, such as afforestation and peatland restoration, nature-based solutions including natural flood management and coastal realignment. Cultural drivers, such as community practices, values and past experiences also may affect the perception of climate risks and adaptation options and responses. For some risks or opportunities in this chapter there are additional factors from changes that occur internationally, especially in sectors where there is international trade. These issues are discussed further in Chapter 7 (Challinor and Benton, 2021) on international risks.

A further development for CCRA3 has been assessment of climate risks and opportunities as they interact with the evolving agenda for Net Zero greenhouse gas emissions (GHG). This is particularly distinctive for the natural environment because of its capacity to sequester carbon, therefore acting to balance other GHG emissions, which include agricultural sources for the land use sector. The CCC report on land use and policies for achieving Net Zero suggested land use options which included increased tree planting; encouraging low-carbon farming practices; restoring peatlands, encouraging bioenergy crops and reducing food waste and consumption of the most carbon-intensive foods (CCC, 2020). It should however be noted that the scope for the natural environment to offset emissions in other sectors is a small fraction of current emissions and is not a replacement for emissions reductions. Chapter 3 identifies some of these options under individual risks, while the synergies and potential trade-offs that will be important for enhanced integration of adaptation actions with the Net Zero agenda are discussed further at the end of the chapter (Section 3.21.1).

The UK Government has put several new Bills before Parliament that will replace existing environmental legislation arising from the UK leaving the EU. The devolved administrations are also involved in developing replacement policies/strategies for their countries e.g., for agri-environment

support. These, together with their associated policies and strategies, will have implications for the risks in this chapter even if climate change is not directly part of their considerations. The desire for a green recovery from Covid-19 similarly would also have implications for the natural environment. The £40 million Green Recovery Challenge Fund in England (which has been increased by a further £40 million), for example, could provide some funding of adaptation for the natural environment, through the themes of nature conservation and restoration or nature-based solutions (Box 3.3), particularly focused on climate change mitigation and adaptation, such as tree planting and restoring peatland, wetlands or coastal ecosystems. Whilst the other theme, connecting people with nature, could help wider engagement with adaptation.

Throughout the chapter the assessment of risk magnitude is primarily based upon expert opinion as supported by review and evaluation of the available evidence. This is consistent with the generic CCRA methodology but recognises the inherent challenges when applying this method to the natural environment which involves both multifaceted risks together with complex systems and processes. The challenge is especially pronounced when interpreting evidence providing quantification of risks which typically only provides a partial assessment of the overall risk, and therefore requires further qualification in the context of the policy-based risk descriptors used to define the chapter structure. For CCRA3, little or no evidence was found of the additional costs and benefits of further adaptation, although many of the risks do suggest that further adaptation is needed.

### Box 3.3: Nature-based solutions

- Nature-based solutions (NbS) are: “actions to protect, sustainably manage and restore natural or modified ecosystems that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits” (Cohen-Shacham *et al.*, 2016).
- NbS include green and blue infrastructure for protecting, sustaining or restoring nature, thus supporting conservation actions. Green and blue infrastructure are an increasingly important adaptation measure and generate a range of benefits both for wildlife (e.g., through habitat creation) and human health (e.g., reducing the Urban Heat Island effect, providing shading and surface water flood resilience; providing recreational opportunities; as well as potentially improving air quality).
- NbS can be used to address a range of environmental, social and/or economic challenges in both urban and rural areas and should provide benefits to human well-being and to biodiversity.
- As NbS involve working with nature, which is multi-functional, they lead to many other co-benefits in addition to the intended outcome(s).
- NbS, therefore, are sectorally cross-cutting and, in the context of CCRA3, interact with other risks and adaptation options.
- In the UK, NbS in particular have been considered for climate mitigation (helping to achieve Net Zero). They are also being implemented as part of adaptation to current and future flooding, where they have been shown to be as, if not more, effective than grey infrastructure for smaller scale flood events (EA, 2018a).
- Currently they have been less explicitly implemented for adaptation for species and habitats, but many ecosystem-based adaptation actions could be considered NbS (Cohen-Shacham *et al.*, 2019). Many NbS are currently quite small scale and need scaling up, in the way that is being considered for climate mitigation (e.g., widespread tree planting), in order for them to make a greater contribution to climate adaptation. They are also often context specific, and this is an issue when trying to scale up to the landscape level. Basing

NbS on an understanding of habitat function should allow a system-scale approach, for example in coastal habitats.

- NbS often are cost effective compared to alternatives, but less is known about their maintenance costs (Keesstra *et al.*, 2018).
- Climate change will impact on the ecosystems and their species in NbS and thus there is a need to ensure that they are resilient to future climate change if they are to continue to provide the functions and benefits which make them a solution to a particular challenge.

### 3.2 Risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion). (N1)

- The magnitude of current and future risks is considered to be large due to the number of species and habitats adversely affected by climate change, both now and in the future.
- There is a range of policies and measures aimed at facilitating adaptation and reducing the impacts of climate change on terrestrial habitats and there are good examples of habitat restoration, which would be expected to build resilience to climate change.
- However, there is a lack of evidence of the effectiveness of these measures to date, while a range of indicators show ongoing declines in biodiversity, which leave species and habitats more vulnerable to climate change impacts.
- There are also few examples of adjustments to manage climate change impacts for the best biodiversity outcomes, when building resilience is not enough to prevent change.
- Several initiatives exist that may reduce climate change risks, but they are not yet finalised and will need to be adequately resourced if they are to make a difference. Thus, the risk is assessed as more action needed.

Since the last CCRA, our understanding of climate change impacts on terrestrial biodiversity has increased, but it has not changed the broad picture of risk and there has been little progress in reducing the factors that increase vulnerability. There is now considerable evidence of the current and likely future effects of climate change and associated drivers on individuals (e.g., their physiology and phenology), populations (composition and abundance) and species (distribution). These combine to affect community and habitat composition and thus the services that they can deliver (Risks N6 and N18). These changes can lead to losses or gains of species in a community or geographic area, whilst changes in distribution can represent threats or opportunities for the receiving area (Risk N3). Risks are therefore different for different species and habitats but given the potential for local or more widespread extinctions and losses, the current and future risks are both assessed to be high magnitude across the UK, with high and medium confidence in the evidence. There is a range of policies and measures aimed at facilitating adaptation and reducing the impacts

of climate change and there are good examples of habitat restoration, which would be expected to build resilience to climate change. However, there is a lack of evidence of the effectiveness of these measures to date, while a range of indicators showing ongoing declines in biodiversity which leave species and habitats more vulnerable to climate change impacts. There are also few examples of adjustments to manage climate change impacts for the best biodiversity outcomes, when building resilience is not sufficient to prevent change. There are a number of initiatives that may reduce climate change risks, but they are not yet finalised and will need to be adequately resourced if they are to make a difference. Thus, the risk is assessed as more action needed.

### 3.2.1 Current and future level of risk (N1)

Note: currently available evidence is not sufficient to allow us to report on the current and future level of risk for each UK country separately.

#### 3.2.1.1 Current risk (N1)

Risks to species from climate change are species-specific. Vulnerability is affected by a wide range of factors, including both the intrinsic attributes of the species and the condition and extent of the habitats where they live (Oliver *et al.*, 2015). Some species are likely to disappear from areas where they are currently found; those at their southern range margin are at highest risk of being lost from parts of their current range as a result of rising temperatures. About a third of studied species are in this category (Pearce Higgins *et al.*, 2017), including many northern species such as the mountain ringlet butterfly and alpine ladies mantle (Natural England and RSPB, 2020). Some species may retreat to higher altitudes (Hubble, 2014; World Museum Liverpool, 2016)

Much of the evidence on movements of range margins comes from more mobile species like birds. Massimino *et al.* (2015) found that, for 80 breeding birds in the period 1994-2009, the leading edge had moved northwards at 3.3 km year<sup>-1</sup>, while the trailing edge had remained largely static. Gillings *et al.* (2015) analysed the range shifts of the distributions of 122 species of British breeding birds during 1988–1991 and 2008–2011 and full range of directional axes. They estimated a 13.5 km shift northwards (see Risk N3), but also a retraction of southern margins. They concluded that the range shifts were multidirectional, individualistic, and probably determined by species-specific interactions of multiple climate factors, with a consequence for change in community composition.

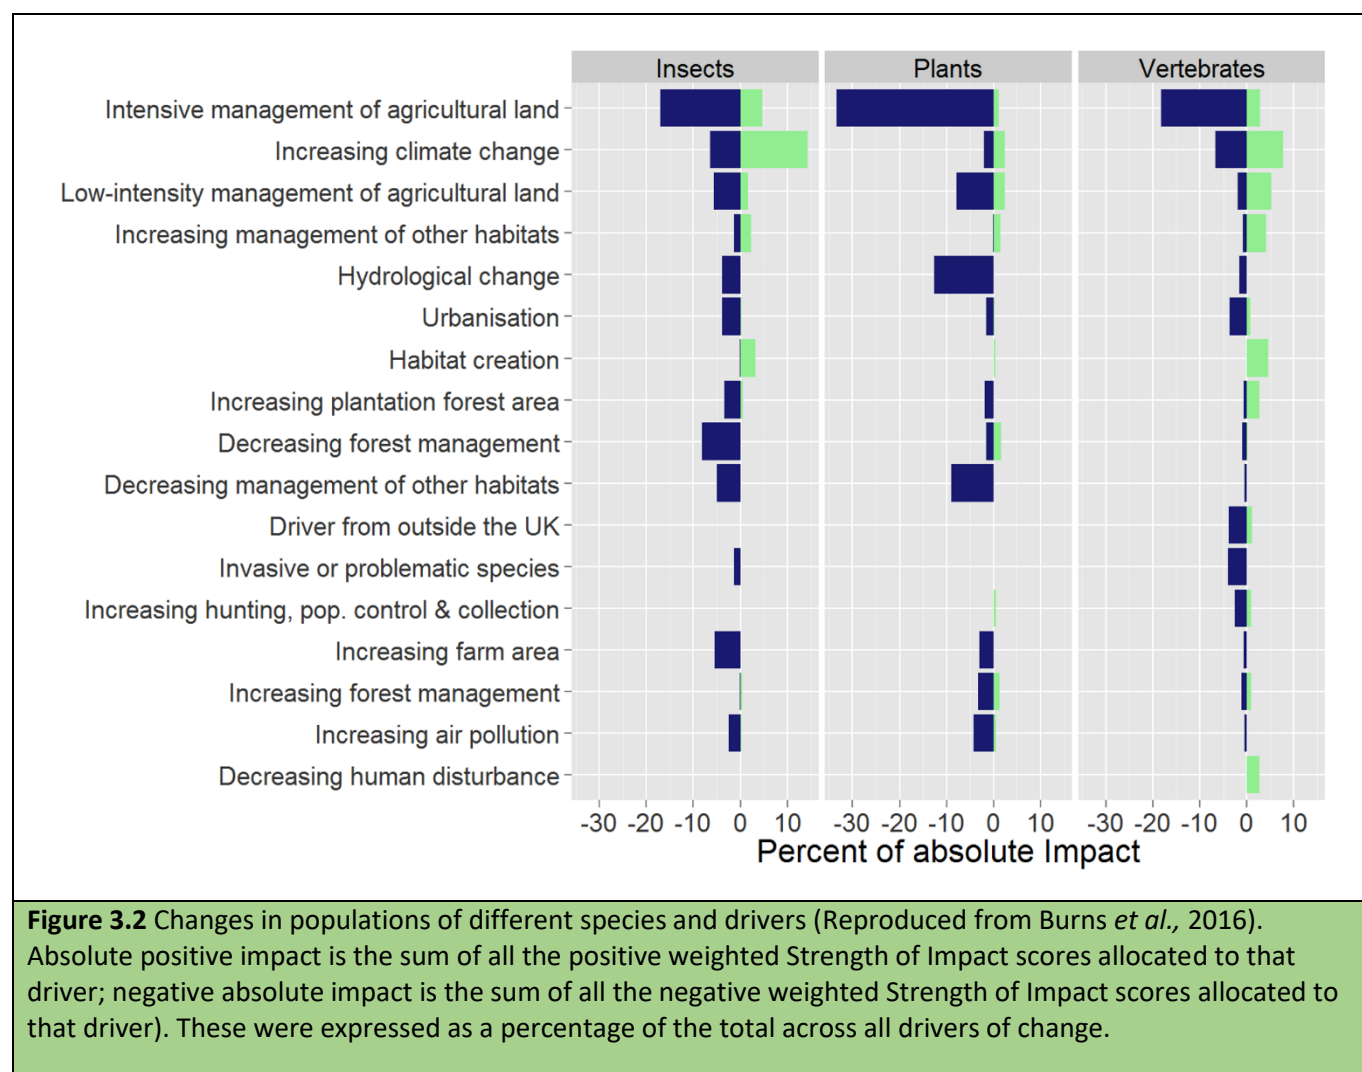

There is new evidence of changes in the balance of different species in communities with southern species tending to increase and /or northern species declining. Climate change may be a contributing factor to the decline of some upland birds (e.g., curlew - 65% decline between 1970 and 2015 across the UK; golden plovers -31% decline 1995 to 2015 in Scotland) through the drying of soils negatively affecting food supplies in their breeding grounds (Hayhow *et al.*, 2017). Also, to the decline of boreal vascular plants, but not boreal bryophytes in southern Britain (Hill and Preston, 2015). Warmer, drier conditions during the spring and summer are potentially adversely affecting food availability and abundance for long-distance migrants e.g., ring ouzel. Changes in bird community composition are mostly affected by the decline in cold loving species (Hayhow *et al.*, 2017), whereas for butterflies it is related to the increase in southern warmth-loving species (Oliver

*et al.*, 2017). In Scotland, overall moth abundance (based on 176 species) decreased by 20% (1975–2014) and by 46% (1990–2014), although their distribution (occupancy) has increased (Dennis *et al.*, 2019). The increasing distribution is likely to be driven by a warming summer climate facilitating range expansion, whereas population declines may be driven by reductions in habitat quality, changes in land management practices and warmer, wetter winters.

There is new evidence of the impact of extreme events, particularly droughts, which are likely to increase in frequency with climate change. At a European scale, Thompson *et al.* (2020) detected a reduction in net carbon uptake (Net Ecosystem Exchange) of ecosystems during the extreme drought of 2018. There are also demonstrable impacts on species and communities with new evidence on the observed impacts on butterflies (McDermott Long *et al.*, 2017, Palmer *et al.*, 2017). While Palmer *et al.* (2017) suggest that extreme climatic events (approximating to low frequency high magnitude events such as heat, drought, flooding) can be associated with some population crashes and explosions of birds and butterflies in England, but that species show individualistic responses.

Species may be affected not just by mean or extreme changes in climate, but also by other drivers acting separately or in combination with climate. A literature and expert-based review of the drivers of change assessed the strength of their impact across 322 species sampled from a broad range of taxonomic groups in the UK (Burns *et al.*, 2016). Each driver was scored by experts on a 1 to 12 scale according to their estimation of its strength of impact on the species and each Strength of Impact score was weighted as if the same number of species had been assessed for each higher taxonomic group (vascular plants, vertebrates and invertebrates). They found that that overall species' population change (~1970–2012) has been most strongly impacted by intensive management of agricultural land and by climatic change (Figure 3.2). The former had the biggest impact on all three taxonomic groups (insects, plants and vertebrates), whilst climatic change was the second biggest for vertebrates and insects, but only the seventh biggest impact on plants. The identified impacts of climate change were a mixture of positive and negative effects. Some of the other drivers were associated with particular groups, for example, the negative impact of hydrological change was relatively greater for vascular plants, whereas the positive impact of habitat creation was relatively lower.

Habitat availability has been shown to be important for species movements at range margins. Platts *et al.* (2019) found that for 13 invertebrate taxonomic groups in Britain, while climate is an important factor in range shifts, half of the variation in rates of range shift could be explained by the interaction between habitat availability and climate change, with habitat availability explaining more of the between-species variation in poleward movement. Also, habitat generalists are expanding more quickly than specialists, but this may be affected by the type of habitats at or beyond the range margin and by the species requirements. Land use is another driver affecting species. Fox *et al.* (2014) found in their examination of the frequency of occurrence of 673 macro-moth species in Great Britain that species with a trailing range margin in northern Britain declined. This is consistent with climate change, but widespread species, which were predicted to be more sensitive to land use than to climate change, declined significantly in southern Britain, where the cover of urban and arable land has increased. Also, moths associated with low nitrogen and open environments declined most strongly, which is also consistent with a land-use change explanation.

Wildfire can result in serious damage to or loss of habitats and species, which may show varying degrees of recovery (Kelly *et al.*, 2016). Climatically, wildfire is linked with hot, dry conditions (ADAS, 2019), but in the UK most wildfire is started by people, as a result of accidental ignition, while the climatic conditions are a predisposing factor. Its incidence is particularly associated with improved

grassland, arable land and woodland (CCC report, 2019; Welsh Government, 2019a), while Arnell *et al.* (2021) identified it with lowland and upland heath. In peatlands and woodlands, it can lead to the release of large amounts of stored carbon.

Coastal habitats around the UK are being affected directly by climate change, as well as indirectly sea level rise, increased saline intrusion, coastal erosion and accretion (Burden *et al.*, 2020) and are covered in risk N17. About 17% of the UK coastline is currently affected by erosion, whilst other areas are either stable or accreting (MCCIP, 2020). These changes are partly driven by sea-level rise, but also by extreme storm events. Habitat loss as a result of 'coastal squeeze' where hard sea defences prevent inland movement of habitats is occurring widely around the UK coast, particularly in low-lying areas with soft rock geology, such as East Anglia.

Climate change is also affecting the phenology (timing of life cycle events) of a range of species, with many (but not all) spring events occurring earlier and autumn ones later (Newson *et al.*, 2016; Donnelly, 2018). This can have consequences for population numbers, ecological processes and food webs. For example, a selection of 130 butterfly and moth species responded positively to ~0.5°C spring warming (1995-2014) in terms of earlier adult emergence, with increases in population growth for species with multiple generations a year, but with neutral or negative effects for those with only one generation a year (Macgregor *et al.*, 2019). The different responses of species also have the potential to lead to mismatches in timings, such as food demand and availability, while lengthening of the growing season could affect productivity and carbon sequestration (Donnelly *et al.*, 2015).

Pollinators are an important group of species for agricultural production, as well as for wild plants. Like many other species, they face multiple pressures, from habitat loss, pests and diseases, extreme weather, competition from invasive species and the use of some pesticides (Vanbergen, 2014; Goulson *et al.*, 2015). Climate change is interacting with these pressures, but the challenges of disentangling climate drivers from multiple stressors means the evidence for its impact remains limited. Modelling using distribution records for 353 hoverfly and bee species, based on 715,392 biological records collected by the UK Hoverfly Recording Scheme and the Bees, Wasps and Ants Recording Society showed that in Great Britain between 1980 and 2013 a third of wild pollinator species (33%) have decreased over this period, approximately a tenth have increased, with the remaining species showing no clear trend (Powney *et al.*, 2019). These losses appeared to be particularly associated with rare species. There was a 55% decline among species associated with uplands in contrast to dominant crop pollinators, which increased by 12%, potentially in response agri-environment measures. The general declines are likely to lead to a deterioration in both wider biodiversity and non-crop pollination services. As noted in CCRA2, climate change is already influencing the range, abundance, and seasonal activity of some pollinator species (Steele *et al.*, 2019). There is increasing evidence of the spring advancement, although increased winter temperatures are affecting queen bee survival. The index of the timing of biological spring events (number of days after 31 December) shows that since 1998, the annual mean observation dates have been around 8 days in advance of the average dates in the first part of the 20th century (Defra, 2020a). Seasonal changes and extreme climatic events could potentially lead to mismatches in plant and pollinator life cycles, to the detriment of both plants and pollinators and the provision of pollination services (Steele *et al.*, 2019).

### 3.2.1.2 Future risk (N1)

A wide range of studies have shown that impacts are likely to increase over the next few decades at least, under all plausible emissions scenarios. It is important to note that many ecological changes take place over long-timescales and with intrinsic time lags (Watts *et al.*, 2020), so processes that are already taking place will result in inevitable ecological changes in the coming years. The larger the change in climate, the larger the impacts, with the potential for far reaching effects which will be hard to adapt to, if global greenhouse gas emissions do not reduce quickly and significantly.

The scale of change will be heavily dependent on the ability of species to physically disperse and adapt to changes in average temperatures, rainfall patterns and seasonality. Many species will only be able to acclimatise or adapt naturally (autonomously adapt) to changing climatic conditions if there is a coherent network of habitats available to them that are in a good ecological condition. Some with low mobility will not be able to shift locations and for some isolated populations e.g., montane, very rare species, dispersal is not possible. There is the potential for genetic adaptation and phenotypic plasticity (Lancaster *et al.*, 2017), but this is unlikely to be sufficient at higher rates of climate change for many species (Parmesan and Hanley, 2015) and some species are likely to be lost. Conservation translocation, in particular assisted colonisation, therefore, may become an increasingly significant tool for some species where natural colonisation is not possible (IUCN SSC, 2013).

A simple assessment of 3048 species using climate envelope modelling and a scenario of approximately 4°C global warming by 2100<sup>1</sup> found that in England, 28% were at risk of range loss by 2070-2099, whilst 54% could have an opportunity to expand their range (Pearce Higgins *et al.*, 2017). A more detailed full assessment of 402 species, included ecological information, such as dispersal and habitat availability, and some species of conservation concern, found that 36% were at risk of range loss, whilst 41% may expand their range. A taxonomic analysis of the risks and opportunities showed considerable variation between groups, with many insects, for example, ants and wasps, showing high levels of projected opportunity, whilst bryophytes and vascular plants had more species at risk (Figure 3.3). Habitat-wise those most at risk were upland species adapted to cool conditions, with a projected decline in suitable climate space for 75% of the species (Figure 3.4).

---

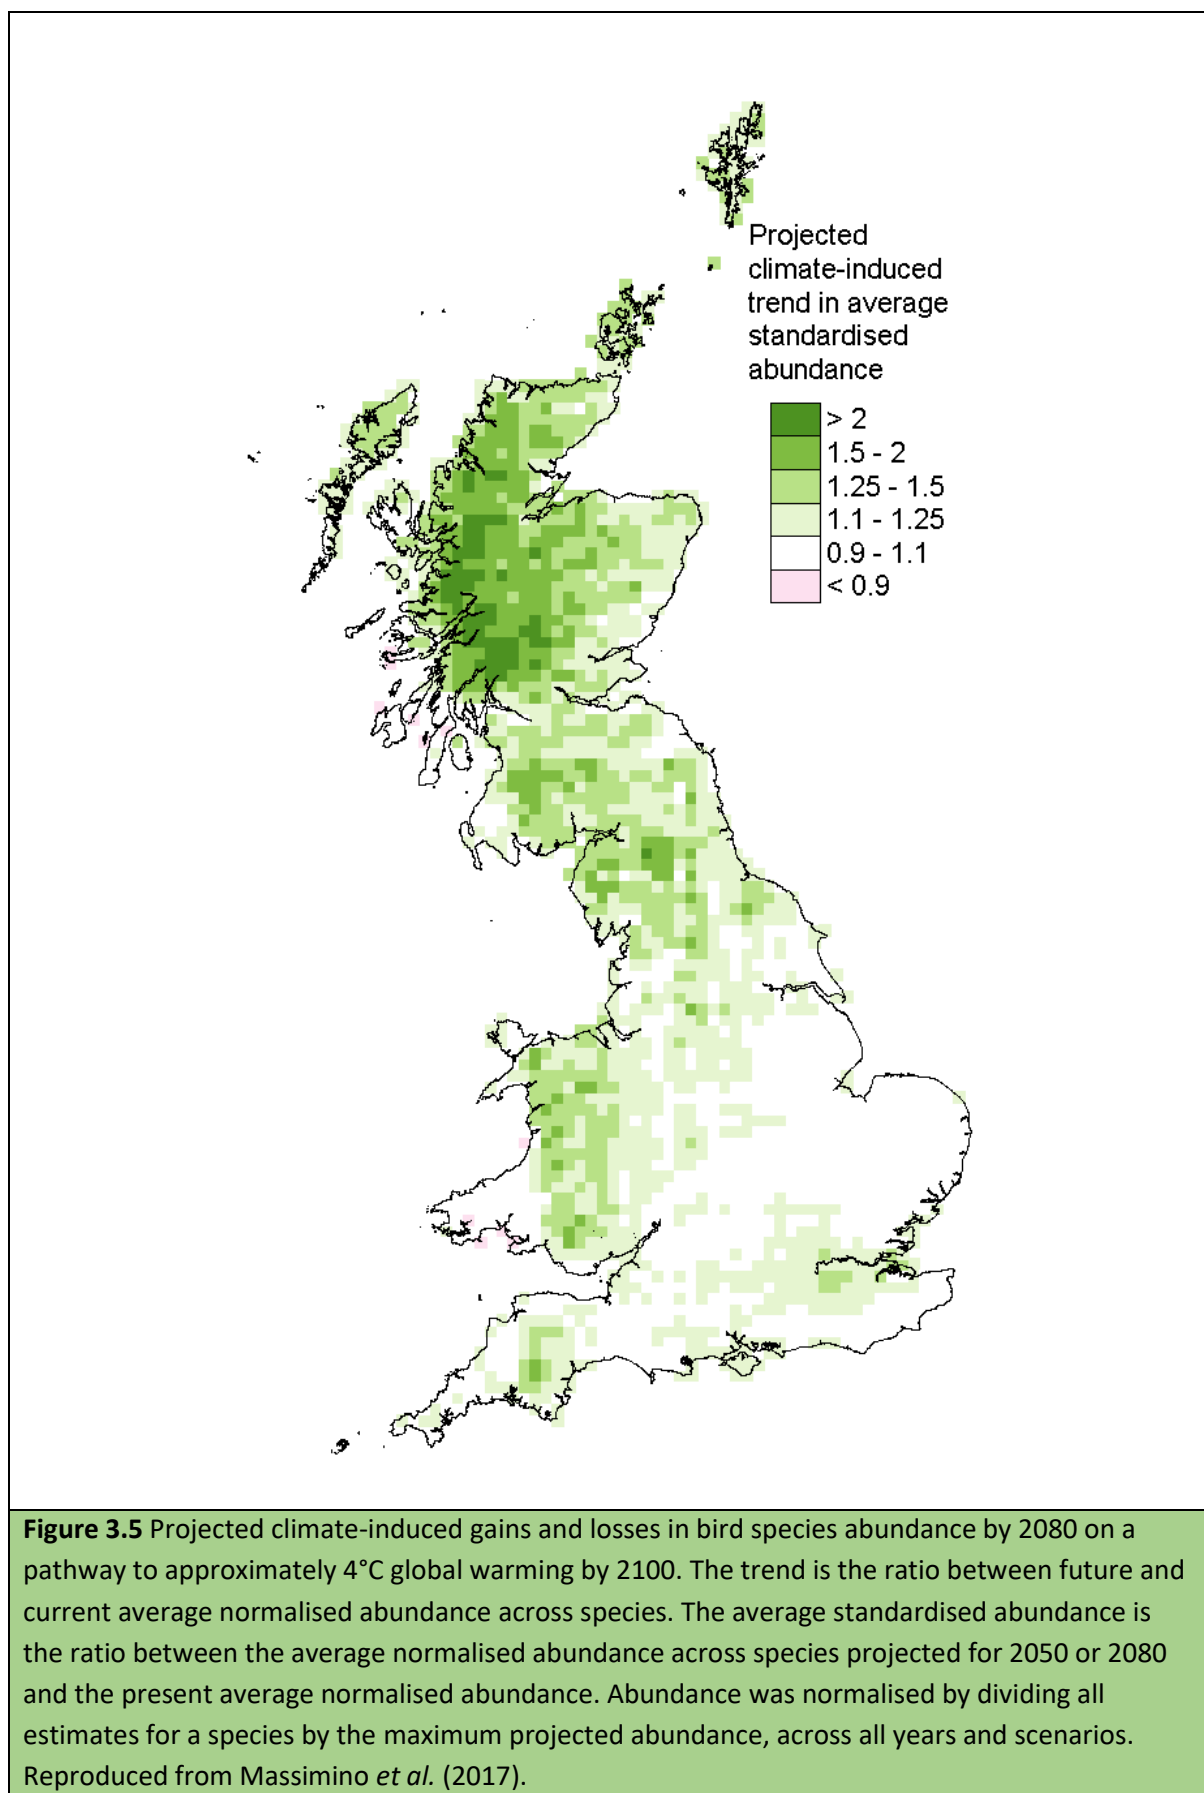

<sup>1</sup> UKCP09 medium scenario (SRES A1B)

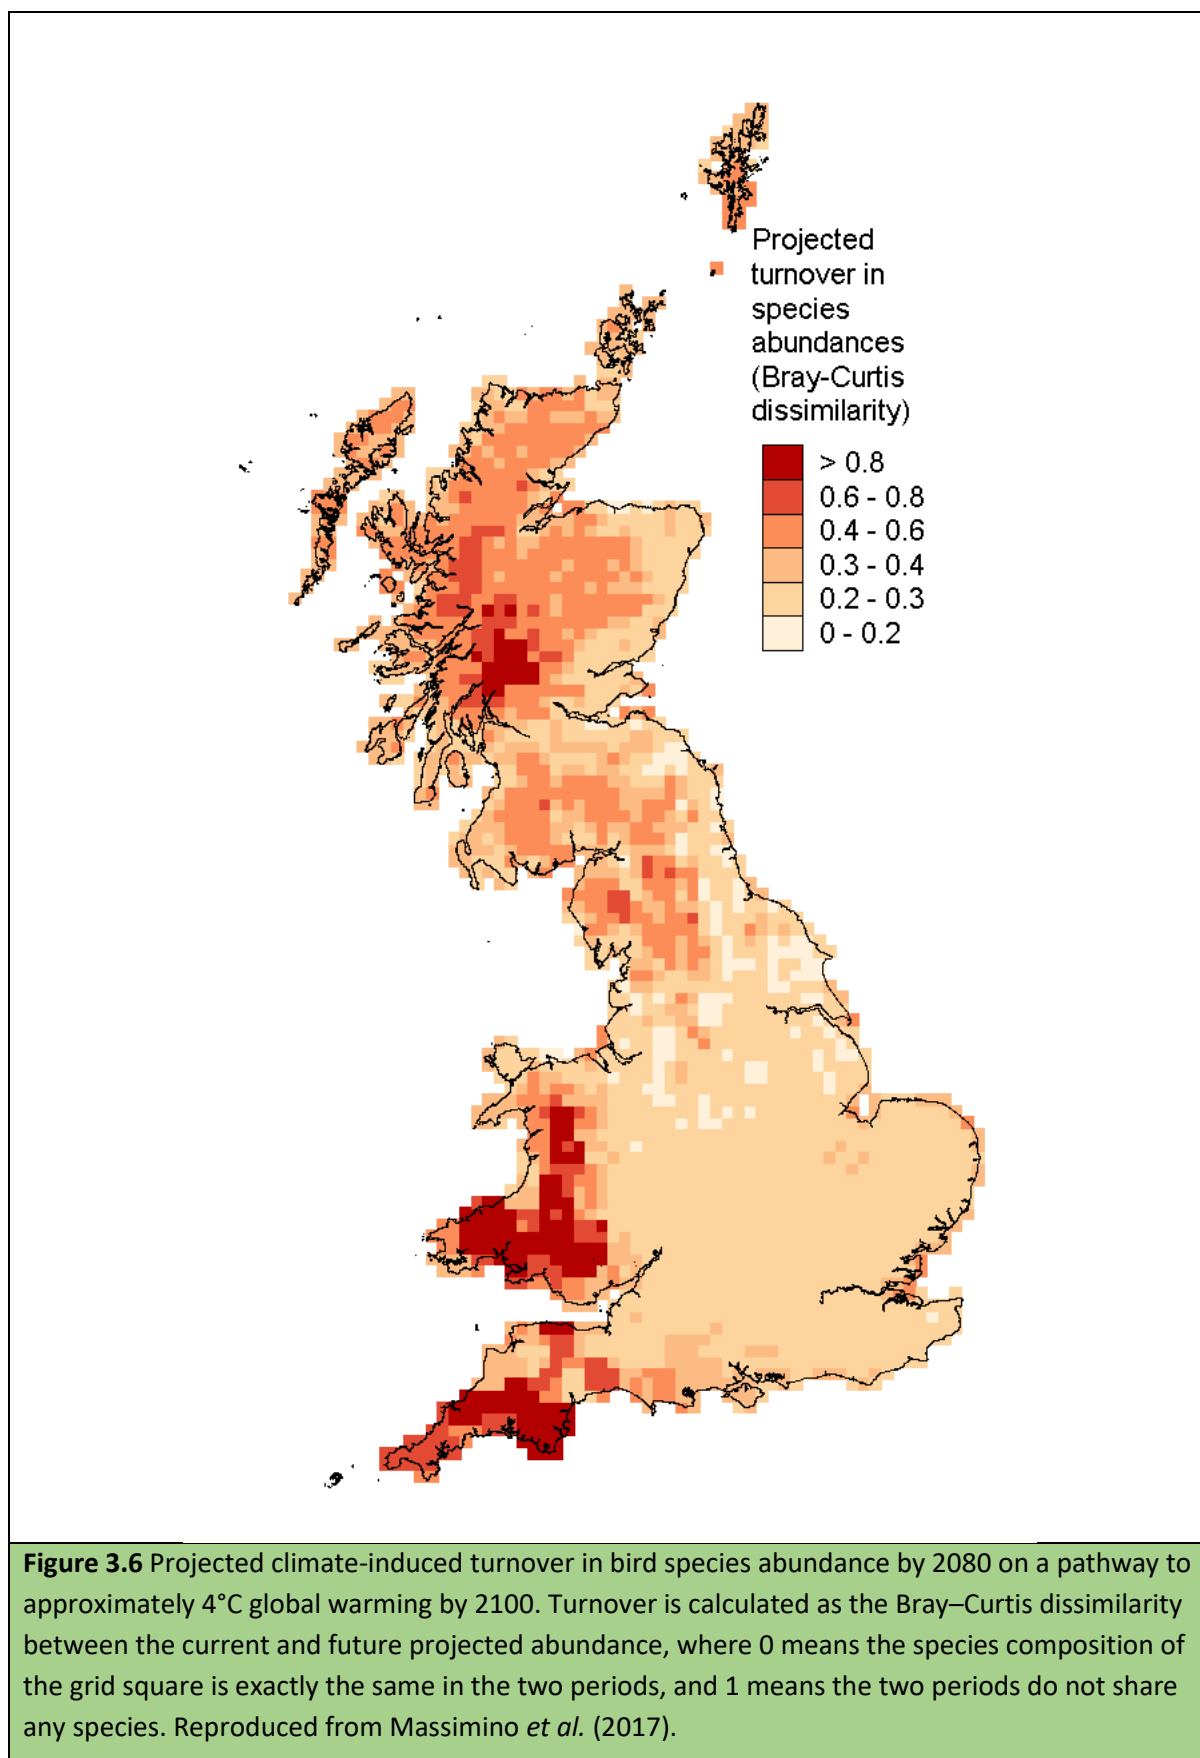

There is however new evidence that these risks can be lower in refugia where topography creates greater variation in the microclimate (Maclean *et al.*, 2015; Massimino *et al.*, 2020). For species at risk in areas that experienced the highest rates of warming, extirpation risk was reduced by 22% for plants and by 9% for insects where refugia were present (Suggitt *et al.*, 2018). Modelling of changes in suitable climate for birds under the future 3°C-rise scenario, combined with current trends in populations, projected that, some birds (such as Scottish crossbill, dotter, purple sandpiper) have a high likelihood of extinction under such an increase (Ausden *et al.*, 2015; Hayhow *et al.*, 2017). Massimino *et al.* (2017), modelling changes in climate suitability for 124 bird species in Great Britain in a scenario of approximately 4°C global warming by 2100<sup>2</sup>, showed that loss of climate suitability could lead to significant population declines for 11 species by 2080 (Figure 3.5). The largest increases are in the north and west, especially in Scotland, probably due to the expansion of more southerly species. Turnover in species abundance is higher in the west of Britain and in the south west, possibly due to the arrival of colonists (Figure 3.6).

<sup>2</sup> UKCP09 spatially-coherent projections with the A1B scenario

Changes in species populations and community composition are also likely within distributional limits including as a result of the changing balance of competition between species and the impact of changing phenologies on foodwebs (Thackeray *et al.*, 2016; Donnelly *et al.*, 2018). The nature of these impacts will differ across the country according to soil type, local climate and microclimates, site management and landscape scale factors, such as the degree of fragmentation of habitats. For example, for the Scottish hare, niche overlap projections<sup>3</sup> with global mean temperature increases of 2°C for 2050 and 3.7°C for 2070 suggest that interspecific competition between European and Scottish hares could become increasingly common, leading to the latter's displacement (Caravaggi *et al.*, 2017). However, the model did not include land use change projections and given the different habitat preferences of Scottish and European hares, it is possible that the competition may be less severe and possibly mediated by habitat management to the benefit of the Scottish hare (e.g., the maintenance of heather moorland and other upland habitats). However, for the Irish hare, while the European hare may pose a short-term threat (i.e., next 30 years), in the longer-term suitable climate space for the two are less likely to overlap in Northern Ireland (Figure 3.7).

More frequent and severe extreme events may also cause local extinctions although niche shifts are an important acclimatisation or natural adaptation response in these circumstances (Roman-Palacios and Wiens, 2020). Droughts and fires are two extreme events that have been particularly

<sup>3</sup> CMIP5 climate projections with the RCP 8.5 concentrations pathway

investigated. In woodlands, future droughts could lead to crown dieback, which in severe cases could lead to tree death (see also Risk N8). High temperatures which are often associated with drought can lead to leaf stomatal closure, which can result in decreased growth, gross primary productivity and transpiration. Models have suggested that drought could lead to changes in woodland productivity, (net) carbon storage and tree composition (Berry *et al.*, 2019). The impacts of drought on managed productive woodland in Britain's forestry sector are covered in Risk N6. Greater risks are associated with repeated occurrence of events preventing recovery. Tree death and decline also has important cultural implications, for example degrading historic parkland, parks and gardens. Drought also affects grasslands and several experimental studies have shown how increasing droughts could affect other organisms, such as soil microbial communities (de Vries *et al.*, 2018) and pollinators (Phillips *et al.*, 2018) with complex effects on the whole biological community. Drought impacts on vulnerable butterfly populations appear to be influenced by the configuration of the landscape (Oliver *et al.*, 2015), with colonies less vulnerable where habitat patches had a lower ratio of edge compared to area (typically indicating a higher proportion of habitat in large blocks).

The risk of wildfire in the future is likely to increase in the UK, with about half of the increase due to rising temperatures and most of the rest to reductions in relative humidity (Arnell *et al.*, 2021). This means that south, east and central regions of England are most likely to be affected, especially in summer, with little change in western Scotland and Northern Ireland, but this partly depends on the scenario and the fire indicator. Short-term experimental evidence suggests that higher severity wildfires as a consequence of more frequent summer droughts could lead to changes in Calluna-dominated raised bog and heathland composition, with implications for ecosystem functioning and services, such as conservation and carbon storage (Grau-Andrés, *et al.*, 2019). The wildfire risk is likely to become greater with increased levels of global warming (Costa *et al.*, 2020).

There could be a reduction or loss of some tree species (e.g., beech, ash) due to pests and disease (see Risk N2), drought, and or winter waterlogging of the root zone. Hedgerows were thought to be most affected by pests and diseases, due to higher summer temperatures (Berry *et al.*, 2019). For moorland, the most significant changes are likely to be caused by hotter, drier summers altering surface water conditions and leading to changes in plant communities. Pests and diseases could also be an issue, with wetter winter conditions leading to the spread of fungi, while the higher temperatures could lead to the upward extension of the range of invasive species (e.g., rhododendron).

In assessing the risks climate change poses to National Nature Reserves in England, drawing on both scientific evidence and the practical expertise of reserve managers, Duffield *et al.* (2021) found that most of the biodiversity features (species, habitats and assemblages) for which the sites were designated were medium or high vulnerability to projected changes in the different climatic variables. The greatest levels of vulnerability were associated with projected changes in extreme events and the combined impacts of climate change. Vulnerability to changes in temperature was assessed to be lower than the other variables. There were, however, differences between habitat types, for example, wetland sites were the most vulnerable to projected changes in rainfall, whereas upland sites were the most vulnerable to temperature change.

In Wales, lowland landscapes (woodland and wetland) are likely to be affected by hotter drier summers, while the generally warmer mean temperatures could increase the effects of pests and

disease on tree cover and hedgerow species (Berry *et al.*, 2019; Risk 18). Similar factors could affect upland grassland. They suggest that upland woodlands are likely to be particularly affected by drought conditions due to hotter drier summers, which may also lead to an increased risk of wildfire. These, along with pests and diseases, may lead to some changes in the mix of tree species, including a reduction in some broadleaved species, such as oak and ash.

Coastal habitats will be affected by both climate change and sea level rise and are covered in Risk N17. Overall, the impacts are assessed as being negative, whilst recognising that on coasts where there is accretion and habitat creation there could be opportunities for habitat expansion.

### 3.2.1.3 Lock-in and thresholds (N1)

Species all have bioclimatic constraints, which are a form of natural threshold. Climate change may mean the current thresholds for suitability for some species are exceeded (as documented above). There are a very large number of different thresholds associated with terrestrial species and habitats, but often these are not documented or only become apparent in extreme conditions, such as droughts. They are also often associated with interactions between species which can be difficult to quantify. Nonetheless, the overall likelihood of threshold levels and thus potentially irreversible effects of terrestrial habitats is greater for higher levels of warming. The CCC Thresholds project (Jones *et al.*, 2020) used a critical temperature threshold of a 30-year mean temperature of 14.5°C for the warmest month and showed that by the 2080s most peatlands in the UK could be modified or highly modified. However, peatland condition is not only affected by temperature, but more often by soil moisture and management factors.

There are important lock-in risks from inaction, because once species or habitats are lost it is much harder to restore them, as not only will species need to be re-introduced, but also complex ecological functioning restored. There are also some related lock-in risks associated with protection or conservation decisions. Protected site designations and boundaries were designed before the threat of climate change was recognised and are relatively inflexible to account for changing habitats and species distributions. Moreover, some boundaries were drawn significantly tighter than guidelines recommend, notably for wetland SSSIs, omitting buffer areas that could prove important for functional resilience. Almost all protected sites are likely to remain important for conservation (Gillingham *et al.*, 2015), but may be valuable for different features other than those for which they were originally designated. The conservation objectives, indicators of favourable condition and site boundaries can all be changed in principle, but in practice doing so is a long and complex process for each of several thousand sites. Duffield *et al.* (2021) showed that Natural England's National Nature Reserves staff recognise the risk of climate change and were taking actions to build resilience, but there was less progress with accommodating change which cannot be prevented. The problem is however recognised and there are some indications that this is starting to be addressed. The UK government has commissioned the JNCC to undertake periodic reviews to ensure that the SPA network continues to support the species for which it has been designated: <https://jncc.gov.uk/our-work/special-protection-areas-overview/-spa-reviews>. In 2015, Natural England published an action plan for climate change adaptation on European protected sites (<http://publications.naturalengland.org.uk/publication/4954594591375360>), although no progress reports on this are available.

Coastal habitats and flood plains are particularly prone to change with rising sea levels (see Risk N17; section 3.21.3.4) but hold the line policies and hard sea defences are a further form of lock in, as they often prevent the coastline readjusting naturally (CCC, 2018a; Welsh Government, 2020), which may lead to the loss of habitats in front of sea defences and also catastrophic loss when sea defences fail (Haigh *et al.*, 2020).

Some land use changes, particularly afforestation, are long-term changes. Planting tree species which are not viable in a particular location in a changed climate could lock-in risk for decades into the future. Planting trees can also present long-term risks to other habitats, both in terms of direct loss or fragmentation and indirectly by preventing the creation of larger blocks of habitat or changing the hydrology of catchments. For example, the Natural Capital Committee (2020) suggest that appropriate spatial planning is needed when tree planting in order to avoid the possible loss of other habitats and land uses, such as species rich grasslands, heathlands and peatlands, especially if they are degraded.

#### 3.2.1.4 Cross-cutting risks and interdependencies (N1)

These include:

- New / increased invasive species and pathogens encouraged by climate change (Risk N2) exacerbating the direct effects on terrestrial habitats and species.
- Abstraction of water exacerbates drought effects by reducing water to support ecosystems.
- Drainage of wetlands has reduced water holding capacity, increasing the risks of drought.
- Canalisation of water courses increases flow rate and reduces water holding capacity of catchments. Similarly, drainage of wetlands has reduced water holding capacity.
- New evidence since CCRA2 on the interactions between land use and climate change, areas with more semi-natural habitat and less fragmentation of habitat show more resilience to climate change and extreme events (Oliver *et al.*, 2015; Watts *et al.*, 2020).
- Flood responses - hard coastal and riverine defences preventing roll back and natural river function, while natural flood management could restore wetlands and improve the conditions of habitats.
- Following drought there may be increased concentration of fertilisers, pesticides and other chemicals, but the peak concentration might happen after the rains return and flow is restored. The drought conditions themselves are unlikely to result in increased concentrations of fertilisers.
- Drought, combined with increased access and engagement could lead to increased risk of wildfire, especially on heathland and grasslands.

#### 3.2.1.5 Implications of Net Zero (N1)

The Net Zero target has the potential to both increase or decrease climate change risks to the natural environment. Changes in land use and management will need to be an integral element of delivering the UK Government's target of Net Zero greenhouse gas emissions by 2050. The specific target differs between the nations, England's is 100% reduction by 2050, while the Welsh Government has also set a Net Zero target for 2050 and the Scottish Government has a commitment

to a target of net-zero emissions of all greenhouse gases by 2045. One commonly advocated climate change mitigation measure is an increasing use of biofuels, including bioenergy with carbon capture and storage (BECCS). Given evidence that intensive management of agricultural land had the biggest impact on plant, insect and vertebrate populations (Burns *et al.*, 2016), an emphasis on productivity of biomass for Net Zero could lead to negative effects. Edible crops (maize, corn) for bioenergy can compete with land for biodiversity and for food crops, (see Risk N6), while an increase in the planting of short rotation forests or coppice can present a threat of habitat loss, although if sited well and carefully implemented this can be reduced.

In order to free up agricultural land for other uses the productivity of remaining agricultural land will need to increase together with a reduction in food waste and the consumption of meat and dairy products associated with high emissions (CCC, 2019a). An intensification of agricultural production could lead to a loss of biodiversity and increased vulnerability to climate change. In Wales, the main developments that will be able to address Net Zero are the new Sustainable Land Management Scheme and National Forest and Peatland Restoration Programme, which will all provide a combination of mitigation benefits linked to Net Zero along with enhancing ecological resilience alongside local/regional green infrastructure initiatives.

Peatland restoration is an opportunity for mitigation and adaptation co-benefits. Many peatlands in the UK have been degraded by drainage, burning, afforestation and conversion to agricultural land leading to high rates of CO<sub>2</sub> emissions (Evans *et al.*, 2017). Even where semi-natural vegetation continues on drained peatland its character is changed, for example with the loss of Sphagnum species. Also, there is an increased risk of wildfire during periods of drought, which can lead to significant carbon loss. Restoration of peatlands, by blocking drainage, removing trees and stopping burning, can reduce and in time prevent emissions at the same time as recovering the biodiversity. Re-wetting peatlands would be expected to improve resilience to droughts, both within the habitat itself and potentially within the wider catchment; it would also be expected to reduce wildfire risk.

Woodland creation and tree planting can be beneficial for biodiversity and adaptation if carried out appropriately. Biodiversity benefits are greater with native species, which are all broadleaves, with the exception of Scots Pine in Scotland. Some tree species and provenances will be better suited to our future climate; this includes a number of native species, such as hornbeam and small leaved lime. A naturally regenerating woodland, rather than a planted one can also maximise genetic variation which increases chances of some individual trees surviving. The concept of nature-based solutions has become increasingly prominent in thinking on climate change adaptation and mitigation. A true nature-based solution addresses societal challenges, such as climate change, with benefits for both people and biodiversity (IUCN, 2016, 2020). For adaptation, planting trees in the right place in a catchment or allowing them to regenerate naturally can contribute to Natural Flood Management (EA, 2018a). Allowing trees and branches to fall and remain on the ground can enhance this effect by creating woody debris dams that slow the flow of flood water. Improving infiltration of water into the soil and reducing the rate at which water drains from catchments, may also help to reduce the impacts of drought events, although there is no evidence to demonstrate this at present.

There is a risk to biodiversity from afforestation if this leads to large scale planting of non-native species or if trees are planted on existing semi-natural habitats; if they are planted on peatlands

(which is limited under the UK Forestry Standard, but still allowed on shallow peat soils) this can lead to emissions of greenhouse gases. Water demanding species also present the risk of reducing water supply in catchments during drought periods. Planting tree species which are not adapted to a changing climate could lead to poor growth rates and increased risk of mortality, particularly during drought events. There are also risks from increased from new pests and diseases (Risk N2; Risk N8). Monocultures of species are more at risk than a diversity of species – a diverse stand reduces the risks of all trees dying or declining. This has implications not just from the perspective of timber yield and carbon, but for biodiversity, as different species of tree support different species of epiphytes, invertebrates and ground flora. Ash dieback, although not caused by climate change, both illustrates the risks and exacerbates the risk of further loss of species; in making decisions about replacing ash in woodlands (Broom and Mitchell, 2017) it will be important to consider the climate change implications.

There is an overarching risk that, because reducing emissions or promoting sequestration is a conceptually simpler problem than adaptation to climate change, decisions will be taken which promote carbon uptake at the expense of adaptation. It is, therefore, important that the impacts of actions deployed to further Net Zero objectives also are evaluated for their impacts on biodiversity and adaptation (Morecroft *et al.*, 2019), as there is potential for adverse effects (both direct and indirect) of afforestation on habitats, for example some wetlands, species-rich grasslands and habitats with organic soils (including shallow peat).

#### 3.2.1.6 Inequalities (N1)

No inequalities associated with climate change were identified in relation to risks and opportunities from terrestrial species and habitats. See Risk N2 for inequalities related to risks from pest, pathogens and Invasive non-native species (INNS).

## 3.2.1.7 Magnitude Scores (N1)

<b>Table 3.2</b> Magnitude scores for risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion).					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (medium confidence)	High  (Medium confidence)
<b>Northern Ireland</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)
<b>Scotland</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)
<b>Wales</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)

Notes: Magnitude categories based on the level of agreement of the evidence and expert judgement of authors (in agreement with CCRA reviewers) of high present day and therefore likely high magnitude impacts on species groups across all four UK countries (category: 'Major impacts on or loss of species groups'). Also, in the context of pollinators, the magnitude is classed as high for all UK countries; 'category: Major impact (10% or more at national level) to an individual natural capital asset and associated goods and services.

### 3.2.2 Extent to which current adaptation will manage the risk (N1)

#### 3.2.2.1 Effects of current adaptation policy and commitments on current and future risks (N1)

##### 3.2.2.1.1 UK-wide

Many generic actions for nature recovery, such as creating bigger, better, more and more connected areas of semi-natural habitats (Lawton Review, 2010), contribute to adaptation in that they build the resilience of ecosystems and can enable species to respond better to climate change. These ‘Lawton’ principles’ have been widely recognised priorities for nature conservation over the past ten years and are starting to influence planning of ecological networks of sites (Crick *et al.*, 2020). To build resilience of ecosystems to climate change this will need to go much further. However, the evidence is also clear that the Lawton principles will not be sufficient in themselves and targeted adaptation actions are needed to tackle specific risks to species and habitats. Statutory and planning processes of conservation also need to change to take account of those inevitable changes in species distributions and habitat features, which we cannot prevent under any adaptation scenario. The significance of climate change risk for the assessment of natural capital (Dasgupta *et al.*, 2021) and the opportunities arising from a natural capital approach also need to be considered in much greater depth.

A number of generic adaptation measures, some of which overlap with general nature recovery, have been recognised for increasing the resilience of biodiversity to climate change (Morecroft *et al.*, 2012; Prober *et al.*, 2019; Natural England and RSPB, 2020). These include: reducing other pressures on biodiversity (Gillingham *et al.*, 2015; Oliver *et al.*, 2017), including agricultural intensification, habitat fragmentation and potentially INNS; increasing the number and size of protected sites (Pavón-Jordán *et al.*, 2020; Eigenbrod *et al.*, 2015; Oliver *et al.*, 2015), as well as providing buffer areas around them; improving the functional connectivity between sites (Keeley *et al.*, 2021); maintaining or increasing habitat heterogeneity; protecting or creating cool microclimates and potential refugia for species (Suggitt *et al.*, 2018) and species translocations (e.g., National Species Reintroduction Forum, 2014; Brooker *et al.*, 2018). An assessment of the drivers of population changes (1970–2012) for 322 species found, conservation measures that might be undertaken as part of climate change adaptation, especially low-intensity management of agricultural land and habitat creation had the most positive impact on insect, plant and vertebrate species (Burns *et al.*, 2016). There is now a reliable evidence base for developing and implementing adaptation plans nevertheless it is important to test the effectiveness of adaptation measures through long-term monitoring, as they take time to achieve their objectives (Morecroft *et al.*, 2019) and this in turn can help to improve adaptation.

The CCRA2 Evidence Report noted that the national adaptation programmes and strategies of all four UK nations recognise the need for adaptation and the need to build ecological resilience (see below). It also stated that increasingly changes will be needed to approaches to conservation management at the site level. Ambitious policy aspirations have been set across all four UK nations to halt long-term declines in biodiversity and improve the condition and coherence of ecological networks (e.g., DAERA, 2019a; Defra, 2018a; Scottish Government 2019; Welsh Government, 2019b). Meeting these targets would do much to improve the resilience of habitats and species to

current and future climate change, and to safeguard the provision of vital ecosystem goods and services. Delivering these commitments on species and habitats and implementing them in a way that plans for climate change adaptation is critical to protecting species and habitats going forward and will require significant investment. This has yet to be committed and past targets have often not been met (for example under Biodiversity 2020 in England; Hawkins *et al.*, 2019). The statutory conservation agencies have produced a large amount of evidence and high-quality advice documents to enable practitioners to adapt to climate change at local scales (see below). This was an important step, but there is a long way to go in delivering adaptation on the ground (Duffield *et al.*, 2021).

Some change in species and habitats is inevitable, for example, in species distributions and the composition of biological communities, even with much more ambitious resilience building and adaptation measures. This will mean that many existing conservation plans for sites and species and the designations of protected areas becoming out of date (Duffield *et al.*, 2021). There are examples of nature reserve management plans being reviewed and adjusted to take account of this in some cases, for example, Natural England and RSPB both have programmes to do this (Natural England and RSPB, 2020). However, this is not happening across most protected areas including Sites of Special Scientific Interest, although there are examples of change at coastal sites where terrestrial habitats are changing into coastal habitats as a result of natural processes or managed realignment. The statutory conservation agencies have produced a large amount of evidence and advice documents to facilitate climate change management (see below).

- i. Elements of all of the national adaptation programmes and strategies support particular generic adaptation measures. Examples for each UK nation are given below related to the following adaptation strategies: Increasing the number and size of protected sites - protected areas (Sites of Special Scientific Interest) have been found to be effective for the species persistence of a selection of birds and butterflies in Great Britain, especially at trailing-edge warm range margins at lower altitudes and latitudes and for species expanding their range margins (Gillingham *et al.*, 2015).
- ii. Habitat restoration – this often involves reducing pressures from other sources and restoring natural ecosystem process. For example, there are a number of relevant schemes for peatland restoration (see Risks N4 and N5) as part of or in addition to the UK Peatland Strategy. It should be noted that climate change shifts the balance of what sort of restoration is important e.g., hydrological restoration will be more important with more droughts and floods.
- iii. Habitat creation - each UK country has targets for tree planting and woodland creation, partly driven by strategies for achieving Net Zero. However, if they are sited and implemented in the right way (ensuring that species planted and management decisions take climate change into account), these activities could help support adaptation, as well as climate mitigation.
- iv. Ecological connectivity – ecological connectivity can be assisted through establishing ecological networks (Crick *et al.*, 2020) and it is supported by policies in all four UK nations.
- v. Translocation/assisted colonisation. This is becoming a more common adaptation response and is starting to appear in policy documents (e.g., see Scottish Government example below).

It should be noted that this does not include some specific adaptation actions, such as the protection of refugia or adjustment of management to take account of changing conditions. Maintaining or restoring cultural landscapes (N18; Chapter 5, H11: Kovats and Brisley, 2021) and traditional land management practices has been an important element of conservation to date. This may be helpful in terms of building resilience of species and habitats associated with these areas, however in some cases traditional practices may need to adapt to changing conditions – for example hay cut may need to take place earlier in the summer.

Each country also has a pollinator plan focused on reducing their loss, summarised below.

### 3.2.2.1.2 England

The 25 Year Environment Plan has a commitment to establish a Nature Recovery Network, which will address ambitious goals including restoring goals both to restore 75% of terrestrial protected sites to favourable condition and to create or restore 500,000 hectares of additional wildlife-rich habitat outside of protected sites. This, if implemented, will contribute to ecological connectivity (linking to both i) and iv) above). Defra is developing an 'England Peat Strategy', linked to the 25-Year Environment Plan, with a vision that all peatlands should be managed sustainably within 25 years. Pollination is included as an important ecosystem regulating function within 25 Year Environment Plan (25YEP) indicators framework under Thriving Plants and Wildlife (D7) and currently is using trends in the distribution of UK pollinators as an interim indicator. The currently delayed Environment Bill contains a number of proposed measures to support nature's recovery in line with the ambition set out in the 25 Year Environment Plan.

At the moment the key delivery mechanism for the aspirations in the 25 Year Environment Plan is the Countryside Stewardship Scheme. This will be replaced by the Environmental Land Management Scheme in 2024, which will also re-direct funding which has to date been allocated to the Single Farm payment, following the model of the EU Common Agricultural Policy. Whether this will deliver the objectives of 25 Year Environment Plan and whether climate change will be adequately addressed is not possible to judge at this stage. This will be a key challenge for the next 5 years – with sufficient funding and full integration of climate change adaptation it could make a transformatory difference, including for landscape scale restoration and rewilding.

A number of other funding channels are available. A key one is the £640m Nature for Climate Fund which will support a range of actions to assist nature-based solutions for climate change mitigation, with a focus on woodland creation and peatland restoration. This also has great potential to support biodiversity and climate change adaptation, particularly if a significant element of native woodland is included and adaptation principles are built into all projects.

An updated adaptation manual for England has been published that embraces the above measures and to support conservation managers in adapting to climate change (Natural England and RSPB, 2020). In addition to enhancing ecological resilience, it recognises the need to prepare for and accommodate inevitable change; valuing the wider adaptation benefits the natural environment can deliver and improve the evidence base.

The Forestry Commission Woodland Indicator includes connectivity as a measure of the size and distribution of patches of forests and woodlands, relative to a value of 100 assigned to 2011. The indicator shows an increase in connectivity for forests and woodlands in England between 2010 and 2017. Over the same period there has been a corresponding increase in the area of forests and woodlands. The change in connectivity may be related to the overall increase in the woodland resource, the location in which new woodlands have been planted (i.e., in relation to existing woodland), or both. Much of the new planting that has occurred has been funded through agri-environment schemes, such as Countryside Stewardship, which encourages applicants to consider connectivity in their plans. The maintenance or restoration of linear features in heritage landscapes (Risk N18) could also contribute to enhancing connectivity.

England's National Pollinator Strategy vision is to see pollinators thrive, so they can carry out their essential service to people of pollinating flowers and crops, while providing other benefits for our native plants, the wider environment, food production and overall human welfare. The Implementation Plan for 2018-2021 considers that success will include: improvements in the condition of protected sites; increases in the extent, quality or connectivity of wildflower-rich habitat outside protected sites and continued uptake of pollinator-friendly agri-environment packages (Defra, 2018b).

#### 3.2.2.1.3 Northern Ireland

Northern Ireland is also restoring its peatlands and other ecosystems, such as ancient woodlands (Climate Northern Ireland, 2019). The All-Ireland Pollinator Plan 2015-2020 (National Biodiversity Data Centre, 2015), which is for the island of Ireland, including Northern Ireland, recognises that pollinators are vulnerable to climate change, but that its impacts on them are difficult to predict. Increasing the connectivity and quality of pollinator friendly habitats are suggested for enabling the movement of pollinators in response to climate change.

#### 3.2.2.1.4 Scotland

Ecological connectivity is part of the monitoring framework to ensure that the natural environment is protected and enhanced (Scottish Government, 2019).

The Scottish Code for Conservation Translocations, for example, has been published to promote the use of best practice (National Species Reintroduction Forum, 2014). An NSIF project led by NatureScot and Royal Botanic Garden Edinburgh is working to identify species for which assisted colonisation and other types of conservation translocation may provide significant benefits. In Scotland, some experimental translocations for threatened alpine species have taken place and have provided evidence on best practice (Scottish Government, 2019). While in Creag Meagaidh National Nature Reserve the feasibility of moving some individuals of the lichen, *Flavocetraria nivalis*, from the high Cairngorms into Creag Meagaidh (which is outside the species' climatic range) is being explored, as a form of assisted colonisation.

The National Peatland Plan aims to support an increase in the annual rate of peatland restoration, from 10,000 hectares in 2017-2018 to 20,000 hectares per year thereafter (SNH, 2015) Also,

Scotland's Peatland ACTION programme has seen significant increases in investment from £3M in 2018/19 to £14M in 2019/20.

The Pollinator Strategy for Scotland 2017-2027 (NatureScot, 2017) sets out how Scotland can continue to be a place where pollinators thrive, along with actions that are needed to help achieve that objective.

#### 3.2.2.1.5 Wales

The Welsh Government has established an adaptive natural resource management framework following from the Environment (Wales) Act which includes establishing resilient ecological networks. A National Peatland Restoration Programme has been published (Natural Resources Wales, 2020), targeting peatland bodies most in need of restoration with the aim of delivering 600-800 hectares of restoration per year. There have been a range of large-scale habitat restoration projects (often EU funded) that are addressing upland peatland e.g., upper Conwy catchment, lowland mires e.g., Sands of Life project which will restore over 2400 ha of sand dunes across four Special Areas of Conservation, on 10 separate sites, as well as compensatory saltmarsh creation through the National Habitat Creation Project. In the Welsh Adaptation Plan under 'Adaptive Nature', there is an action to develop functional resilient ecological networks, with a database to be combined with ecosystem service assessment (Welsh Government, 2019b).

The Wales Action Plan for Pollinators (2013) sets the strategic vision, outcomes and areas for action to improve conditions for pollinators and work to halt and reverse their decline in Wales. A review of the plan was published in 2018 (Welsh Government, 2018b) and adds additional actions. Although the original plan did not include a specific action around climate change, the review document does detail where the action plan has been of benefit to adaptation for pollinators and sets out future actions such as Pennal 2050. The plan also sets out actions to reduce pressures on pollinators from other sources (land-use intensification, habitat destruction and fragmentation, disease, the use of agro-chemicals). The need to protect and improve conditions for pollinators is recognised in Natural Resources Wales' Area Statements for Wales, an important part of Wales' Natural Resources Policy. Part 2 of the Wales Nature Recovery Plan has also been refreshed for 2020-2021 to address issues driving the decline in biodiversity, including climate change.

The role of flood risk management and water quality for supporting terrestrial habitats and species is also recognised under the National Strategy for Flood and Coastal Erosion Risk Management in Wales (Welsh Government, 2020), setting out many actions to build flood resilience in otherwise impacted habitats. Water Resource Management Plans and River Basin Management Plans also provide policy in Wales for habitat protection from a water resource perspective.

#### 3.2.2.1.6 Impacts of EU-Exit and Covid-19

At the present time the policy and legal framework for support of biodiversity is changing, largely driven by the UK's exit from the European Union. The details of the new policies and legislation that are being developed have not been finalised, so it is not possible to assess their likely effectiveness in helping address adaptation. The level of funding for sustainable land management and the rules

concerning how it is spent will also be critical to how much is achieved and thus there is a risk of insufficient government funding to enable nature recovery. In our view there could also be a risk that EU-exit could lead to the lowering of environmental protection standards to enable trade deals with other countries.

Covid-19 has led to, at least, a short-term loss of income for NGOs, leading to decreased conservation action from them. However, the £40 million Green Recovery Challenge Fund might help, although it is probably not sufficient for the level of nature recovery needed. Biodiversity is viewed as part of a green recovery, helping to address risks to society and the economy, but needing a number of actions including the scaling up of investment in biodiversity conservation, its sustainable use and restoration (OECD, 2020). This report also recognises that the challenges of addressing climate change and biodiversity loss are closely related.

Covid-19 has led to more people spending time outdoors, possibly resulting in greater environmental engagement, as well as the realisation of the importance of the natural environment, especially to human health and well-being. Although at the same time, there has been large scale reporting in the media of damage to landscapes from increased litter and footfall (e.g., <https://www.bbc.co.uk/news/uk-england-cumbria-53693300>). While at some sites there is a suggestion that the lack of human disturbance has led to improvements in biodiversity (e.g., <http://www.msn.com/en-gb/news/uknews/endangered-species-of-seahorse-returns-to-former-stronghold-due-to-lockdown/ar-BB14URMj?ocid=ientp>).

### 3.2.2.2 Effects of non-Government adaptation (N1)

Acclimatisation and natural adaptation will take place (as discussed above), but our view is that this is insufficient to address the adaptation gap. Some of this shortfall will be addressed by non-Governmental stakeholders, as many are undertaking adaptation relevant actions. There are a considerable number of projects undertaken by the RSPB, National Trust, Woodland Trust and DA Wildlife Trusts (e.g., Living Landscapes and Futurescapes). These are delivering improved habitat management or restoration that will enhance resilience. For example, the National Trust is involved with a range of projects for the research, restoration and management of peatlands in England and Wales and is intending to restore or create 3,269 hectares of peatland habitat, of which 2,070 hectares is underway and 665 hectares is complete. While in Northern Ireland, under the INTERREG funded Collaborative Action for the Natura Network, Ulster Wildlife have been re-wetting over 1000 ha of peatland.

There are also a number of other initiatives, such as rewilding, which may involve private landowners. This involves a more ecosystem approach to the restoration of habitats and natural processes, as well as often trying to address issues of connectivity to facilitate reactive adaptation.

### 3.2.2.3 Barriers preventing adaptation (N1)

There are a number of barriers and constraints to adaptation (relevant to all risks in this chapter), which make it difficult for organisations (public and private) to plan and implement adaptation actions (Cimato and Mullan, 2010; HMG, 2013). These various barriers can make it difficult to make

decisions or take action, even when it is clear that action is needed. They include uncertainty, which translates through to the market failure of imperfect information. Further, many adaptation actions – especially for the natural environment – have a public goods or non-market dimension in which the private sector is unlikely to invest. The available resources to adapt is often an issue. There are also policy, institutional and governance barriers to adaptation, which may make it harder for Government to implement adaptation, or to create the enabling environment for the private sector or individuals to adapt.

Currently, our view is that the policy framework is in place with appropriate conservation objectives but lacks coherent delivery of widespread landscape-scale adaptation that not only builds ecologically resilient networks, but also ensures that wider environmental benefits are achieved. This is likely due to a combination of the barriers above.

Resources, in particular limited conservation budgets, are also a constraint on implementing adaptation actions, so other, innovative, sources of funding need to be found. There are an increasing number of options and one option could involve conservation organisations developing finance-ready proposals for investment in biodiversity through green finance (RSPB, 2018).

Land availability for habitat creation and networks can also be a constraint as there are many competing demands on land to provide food, timber, bioenergy, recreation etc. However, agri-environment schemes could increase the engagement of landowners in conservation activities and enhance species resilience and adaptation potential for climate change e.g., restoring/creating new habitats, such as hedges. While Net Zero offers the potential to increase resilience and build climate change adaptation into land management, it is essential to ensure that species and habitat priorities are accommodated, perhaps by using a more systemic nature-based solutions approach to achieving Net Zero in land use and agriculture.

#### 3.2.2.4 Adaptation shortfall (N1)

Plans are in place in all the UK nations (see above) that contain targets, which if met, would make significant steps in halting and reversing decades of degradation and fragmentation of the natural environment in the UK and thereby facilitating adaptation. However, at the time of writing it is not clear that the various aspirations in the plans are on track to be met. Current plans and targets could benefit from a more specific set of actions for climate change beyond habitat condition, which could include more on planned site alteration to address climate threats (drought, flood, wildfire), spatial planning at small scale (allowing species to move) and large-scale networks. Funding schemes to replace the Common Agricultural Policy (CAP) post EU-Exit also need to take steps to ensure that actions to reduce vulnerability and exposure to climate change are rewarded. As climate change continues, a commitment to review regularly and if necessary, adjust the boundaries and/or the conservation objectives of protected sites, species objectives and the indicators of favourable condition would facilitate adaptive management. As such, our view is that the risk is being partially met across the UK (Table 3.3), but further action would help to meet the adaptation shortfall by ensuring targets are on course to be met, and putting in place further policies for land management that support adaptation post EU-Exit.

## 3.2.2.5 Adaptation Scores (N1)

<b>Table 3.3</b> Adaptation scores for risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion)			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Medium to low confidence)	Partially (Medium to low confidence)	Partially (Medium to low confidence)	Partially (Medium to low confidence)

## 3.2.3 Benefits of further adaptation action in the next five years (N1)

The CCRA2 Evidence Report concluded that further action is needed now and into the future to increase current efforts to reduce existing pressures, improve the ecological condition of protected wildlife sites, and restore degraded ecosystems, such as peatlands, wetlands and native woodlands. There is a window of opportunity to build the resilience of habitats, through a range of measures that will improve the capacity of species and biological communities to persist and adapt. This is important as once species or habitats are lost it is much harder to restore them, as not only will species need to be re-introduced, but also complex ecological functioning restored, if that is even possible. Ecological restoration can take many decades for some habitats, meaning that there are long lead-in times for adaptation action. This has not changed and there is a need to take more flexible and integrated approaches to managing natural capital, including further realignment of the coast, catchment-scale management strategies, and landscape- scale initiatives to increase habitat extent and improve habitat condition and connectivity.

Climate and environmental change, therefore, should also be more explicitly accounted for in conservation planning at the site level and more widely. This may include modifying conservation objectives and planning for and anticipating necessary changes in spatial distribution, for example by identifying and securing refugia. Site level conservation objectives and plans would benefit from being reviewed to assess whether management is appropriate for new or potential colonists and adapted accordingly. It is important that planning begins in time for action to be effective.

Increasingly the link is being made between climate change and biodiversity loss, with nature-based solutions being an important way of addressing these two together (see Box 3.3; Section 3.21.2). Nature-based solutions will help deliver adaptation actions including: developing resilient ecological networks; increased canopy cover and well-located woodland for greater habitat availability and ecosystem service value; maintaining, enhancing and restoring floodplains and hydrogeological systems to reduce flood risk and improve water quality and quantity; restoration of uplands and managing them for multiple benefits.

### 3.2.3.1 Indicative costs and benefits of additional adaptation (N1)

The valuation of the impacts of climate change on terrestrial species and habitats is challenging, and this makes it difficult to analyse the subsequent benefits of adaptation in reducing these risks. It is also highlighted that while the literature on the costs and benefits of adaptation is improving, there is very little information on the costs and benefits of helping natural systems adapt (Tröltzsch *et al.*, 2018). There has been some analysis on the costs and benefits of peatland restoration (Moxey and Moran, 2014; Bright, 2019, Watkiss *et al.*, 2019), which indicate that restoration is generally worthwhile in most (but not all) cases, for both upland and lowland peatlands (i.e., with positive benefit cost ratios). The benefits increase if more ecosystem services are able to be valued (and this is a general issue for many risks in this chapter) and climate change strengthens the case for restoration. There are some case studies on cost-effectiveness or cost benefit analysis of buffer zones, migration corridors and even translocation for specific habitats or species (e.g., Tainio *et al.*, 2014) though this remains a gap (especially on the benefits analysis). Finally, there would seem to be a strong economic case for an expanded role for Government intervention to provide enhanced monitoring and surveillance and early response.

### 3.2.3.2 Overall urgency scores (N1)

**Table 3.4** Urgency scores for risks to terrestrial species and habitats from changing climatic conditions and extreme events, including temperature change, water scarcity, wildfire, flooding, wind, and altered hydrology (including water scarcity, flooding and saline intrusion).

Country	England	Northern Ireland	Scotland	Wales
Urgency score	More action needed	More action needed	More action needed	More action needed
Confidence	Medium	Medium	Medium	Medium

There is much evidence of the current and potential risks of climate change to terrestrial ecosystems as set out above and while there are extensive current and planned adaptation measures there is a gap in understanding how aspirational targets that are set out in policy are planned to be met through actions, as well as a continuing lack of evidence on how actions are reducing vulnerability and exposure. A potential trade-off that also needs to be considered is the potential risks from mitigation options for Net Zero that are implemented without sufficient regard for maintaining or enhancing biodiversity in its adaptation to climate change.

Thus, the risk remains High and more action is needed.

### 3.2.4 Looking ahead (N1)

Given the state of flux around many policies following EU-Exit, decisions made in the next few years could have a profound effect on the natural environment for decades to come. Much of the UK's natural environment is degraded with many species at risk and successful adaptation will not be

possible without a significant investment in restoring natural areas. Equally, investment in nature recovery will be at risk if climate change adaptation is not fully embedded into planning from the start. It is essential that adaptation is consistently factored into decision-making alongside climate change mitigation and the protection of biodiversity from the start. It will also be essential to embed the concept of nature-based solutions at the heart of climate change adaptation across other sectors, including agriculture, flood risk management, water supply, infrastructure and urban planning. The opportunities for co-benefits are high but there are also serious costs if this does not take place. There are good indications that these issues have been recognised in policy development, but as yet the mechanisms for delivery are unclear and the level of funding undetermined: the risks to people and nature are serious and the cost of addressing them should not be underestimated.

There is limited evidence on the effectiveness of adaptation actions in this area and it is intrinsically difficult to assess the extent to which harm has been avoided, especially given the long timescales over which both climate change and ecological processes operate. Consistent, long-term monitoring and assessment will be important to inform adaptive management and build a robust evidence base for further action.

### 3.3 Risks to terrestrial species and habitats from pests and pathogens, including Invasive Non-Native Species (N2)

- Despite strong international and national policy frameworks for managing the risks to terrestrial species and habitats from pests and pathogens, these risks are expected to continue increasing. Support for INNS is generally less well developed and resourced than for other pests and pathogens.
- Current risk assessment and management measures provide some adaptive capacity to reduce these risks, but there is a compelling need for enhanced monitoring, surveillance and early response measures to prevent a spread.
- The magnitude of current and future risks is assessed as medium, but high for future risks in England, based on the combination of its closer proximity to continental Europe and generally higher temperatures which result in a higher likelihood of incursions of some INNS prevalent in Europe and their establishment in warmer areas of England. The magnitude score is high for all countries in the 2080s under a 4°C world.
- These risk levels could change with improved understanding of the specific climate responses and thresholds of high-risk pests and pathogens, and the potential change in risk associated with adaptation options.

#### Introduction

The introduction, establishment and spread of pests and pathogens, including Invasive Non-Native Species (INNS), and the risks they pose to terrestrial species and habitats involves complex interactions between biotic and abiotic factors. Changes in these risks are primarily influenced by socioeconomic drivers, including cross-border trade, within-country movements, biosecurity measures and land use change. Climate variability and change is generally considered a second order

influence on these risks through its impact on the life cycle and spread of pests and pathogens, or incursion and establishment of INNS. In recent years, warmer winters have had a clear influence on outbreaks and incursions of some pests and pathogens in the UK. UKCP18 climate projections show continued warming and changing patterns of extreme events across the UK, which is expected to expand the range of climate suitability for many pest and pathogen species and increase the chance of establishment of INNS, thereby increasing the future risk to terrestrial species and habitats.

### 3.3.1. Current and future level of risk (N2)

Note: currently available evidence is not sufficient to allow us to report on the current and future level of risk for each UK country separately.

#### 3.3.1.1 Current risk (N2)

Pests, pathogens and INNS have the potential to disrupt key ecosystem functions and cause significant economic damage. They threaten individual species or whole habitats and can severely impact a range of ecosystem services, e.g., carbon storage and biodiversity, and cultural heritage, e.g., parks, gardens and designed landscapes. Evidence of recent increases in the number and severity of outbreaks of native pest and pathogen species, and establishment of INNS, indicate that risks to terrestrial species and habitats have continued to increase since CCRA2. Increasing international trade, especially in high-risk products such as horticultural plants and wood packaging, has been a primary driver for the rise in INNS introductions. For example, in July 2019, 60 sites across UK were exposed to oak processionary moth (*Thaumetopoea processionea*) caterpillars imported with oak trees from the Netherlands and Germany (<https://www.forestresearch.gov.uk/tools-and-resources/pest-and-disease-resources/oak-processionary-moth-thaumetopoea-processionea/>). Low probability high impact events, such as multiple high-risk pest or pathogen outbreaks in close succession across the UK, could cause major agricultural losses and disruption, from which it would be challenging to recover.

Recent warmer winters across the UK have favoured the survival and development of many pests and pathogens, and incursion and establishment of INNS. For example, in July 2019, an outbreak assessment by the Animal and Plant Health Agency (APHA) on the bluetongue virus serotype 8 strain (BTV-8) noted that warm conditions in the UK and northern Europe at that time were favourable for both adult *Culicoides* midge activity and bluetongue virus replication within the midge vectors (Defra, 2019b). Native UK tree species are particularly at risk. For example, from its first discovery in the wider UK environment in October 2012, the spread of ash dieback disease by the *Hymenoscyphus fraxineus* fungus continued rapidly, covering 61% of the UK landmass by 14<sup>th</sup> May 2020 (<https://www.forestresearch.gov.uk/tools-and-resources/pest-and-disease-resources/ash-dieback-hymenoscyphus-fraxineus/>). In Scotland, two of the most significant risks to forest resources and woodland biodiversity come from *Phytophthora ramorum*, a fungus-like pathogen that is a particular threat to larch, and *Dothistroma* needle blight (DNB), which poses a particular threat to Scotland's commercial forestry and also to native Caledonian pinewoods. Although the causes of recent increases in DNB are currently unclear, some evidence suggests that increased rainfall in spring and summer coupled with warmer springs have optimised conditions for spore dispersal and infection (Brown and Webber, 2008). The juniper disease, *Phytophthora austrocedri*, first confirmed

in the UK in 2011, has also spread rapidly to sites across northern England and Scotland (<https://www.forestresearch.gov.uk/tools-and-resources/pest-and-disease-resources/phythophthora-austrocedri/>). On the island of Ireland, ash dieback was first identified in October 2012 and had been detected at 306 sites (195 in Republic of Ireland and 111 in Northern Ireland) by 2017 (McCracken *et al.*, 2017). The vast majority of outbreaks were on young, imported trees, although it was also noted that the pathogen cycled within a plantation or moved to infect neighbouring hedgerow trees. A study of hedgerow trees in Northern Ireland highlighted the general poor condition of many hedgerow trees, especially ash due to canker, threatening the ecosystem services provided by hedgerow standard trees (Spaans *et al.*, 2018). Also, a study of the declining health of alder trees along the river Lagen in Belfast noted serious disease from various *Phytophthora* species, including the first report of *Phytophthora lacustris* in Northern Ireland (O'Hanlon *et al.*, 2019). Other important diseases threatening woodland ecosystems in general are *Phytophthora alni* and oak decline (<https://www.forestresearch.gov.uk/tools-and-resources/pest-and-disease-resources/>). A detailed review of forest and woodland pests, pathogens and diseases is available in Section 3.10.

Invasive non-native (plant and predator) species can create risks and opportunities for pollinator nutrition and reorganise species interactions to affect native pollination and community stability (Vanbergen *et al.*, 2018). Currently there are comparatively few recorded accounts of alien plant invasions in the UK consistently lowering pollinator diversity or abundance (Steele *et al.*, 2019), but there are a large number of knowledge gaps and it is not clear what role climate change has had in their arrival or spread.

The UK Plant Health Risk Register (UKPHRR) provides a major resource for assessing current and future pest and pathogen risks (<https://secure.fera.defra.gov.uk/phiw/riskRegister/>). It was developed by Fera and Defra in 2013 based on recommendations of the independent Task Force on Tree Health and Plant Biosecurity and launched in 2014. The UKPHRR records and rates risks to UK crops, trees, gardens and ecosystems from plant pests and diseases and currently (29<sup>th</sup> January 2021) includes records of 1227 pests and pathogens. It provides a framework for decisions on priorities for actions by government and plant health stakeholders. For example, the number of high priority forest and woodland pests derived from the UKPHRR is utilised as one of the Forestry Commission Key Performance Indicators (Forestry Commission, 2020a).

Official statistics from the UK Biodiversity Indicators (Defra, 2020a) show a progressive increase, since 1960, in the number of INNS recorded in freshwater, marine and terrestrial environments across Great Britain (Figure 3.8), which is likely to have increased pressure on native species and habitats (Harrower *et al.*, 2019). Of the 3,208 non-native species recognised and recorded in Great Britain from 1960 to 2018, 62.5% are classified as established (reproducing in the wild) and 193 species are thought to exert a negative impact on native biodiversity (46 freshwater species, 39 marine species and 108 terrestrial species). Terrestrial environments have seen the highest number of recorded INNS, 58, between 2010 and 2018.

The Global Assessment report on Biodiversity and Ecosystem Services identifies INNS as one of the top five threats to biodiversity worldwide (IPBES, 2019). The UK Biological Security Strategy (The

Home Office, 2018), which brings together cross-Government initiatives to protect the UK and its interests from significant biological (human, animal and plant) risks, notes that between August 2000 and December 2017 there were 22 outbreaks of exotic notifiable animal diseases in the UK that cost the Government between £300,000 and £3 billion. INNS potentially cost the UK economy £1.7 billion per year (£1.3 billion to England, £0.24 billion to Scotland and £0.13 billion to Wales) (Williams *et al.*, 2010).

CCRA2 highlighted risks from pests and pathogens as a priority area for future research (CCC, 2017. Although there has been further research, especially on high-risk pest and pathogen species, it is not clear from the evidence whether subsequent research was directed based on the CCRA2 recommendation or in response to heightened risk status.

### 3.3.1.2 Future risk (N2)

Risks from pests and pathogens are expected to continue increasing across all UK countries in response to expanding trade and changing climate. Uncertainties relating to post-EU-exit trade agreements and cross-border biosecurity cooperation, especially between EU nations, make it difficult to assess the future level of risk. A level of continuity has been assured by a Government statutory instrument, included under the correcting powers set out in Section 8 of the EU Withdrawal Act 2018, which ensures maintenance of existing INNS safeguards for those species listed on the EU Invasive Alien Species regulation after EU-exit (<https://www.theyworkforyou.com/lords/?id=2019-01-22a.662.3>). Existing domestic regulations will continue to safeguard against other INNS not covered by this EU regulation. Increased imports of high-risk commodities, such as wood products and live plants (especially exotics), or from regions with high pest or pathogen prevalence, would increase the chance of INNS entering the UK and potentially becoming established. For example, in 2012 an outbreak of Asian Longhorn Beetle (*Anoplophora glabripennis*), a native of Southeast Asia and serious pest of broadleaved trees, was discovered in Kent, England, and attributed to untreated wood packaging from a nearby business importing stone from China (Straw *et al.*, 2016).

COVID-19 poses additional challenges and uncertainties for managing pest and pathogen risks, particularly ensuring biosecurity measures are maintained to safeguard the UK food supply chain whilst ensuring the safety of surveillance teams involved. As well as guidance and support provided by UK Government, specific guidance has been provided by pest management organisations, including “Becoming COVID-19 secure” by the British Pest Control Association (BPCA, 2020). Recent updates to the UK climate projections, UKCP18 (Lowe *et al.*, 2018 Murphy *et al.*, 2018), highlight continued warming and changing patterns of extreme events across the UK, which will impact on the life cycles and population dynamics of many pests and pathogens, as well as host species (Boggs, 2016). Warming is likely to expand the range of climate suitability for many species and increase the chance of establishment of INNS in the UK, particularly for species that have shown recent northward expansion across Europe. For example, Bradshaw *et al.* (2019) projected that with 2°C - 4°C global warming<sup>4</sup> there is a high risk of the tobacco whitefly (*Bemisia tabaci*) becoming established in the UK. Milder winters are also expected to encourage overwintering and expansion of species currently limited by cold temperatures, such as Diamondback Moth (*Plutella xylostella*) (Wainwright *et al.*, 2020). *Xylella fastidiosa* is also a significant future risk with multiple plant host species of economic and environmental importance (White *et al.*, 2019). Future climate changes are also likely to increase stress on some terrestrial species and habitats, which can lead to reduced resilience to other stresses, including pest or pathogen attack (Dutta *et al.*, 2020).

Many pests and pathogens respond to thresholds of temperature, moisture availability and wind (speed and direction), which are some of the more uncertain climate parameters in future climate projections. Life cycle and phenology responses occur at community scales, and are, therefore, subject to community effects, such as competition, as noted for non-pest species (see Risk N1).

---

<sup>4</sup> HadGEM3A-GA3.0 atmosphere model driven by sea surface temperature patterns from 6 CMIP5 projections, using timeslices at 2°C global warming as described in Betts *et al.* (2018) and at 2°C global warming using the same method.

Continued climate changes may also induce complex interactions between pests/pathogens and their host species, leading to compound responses. For example, with simulations of the productivity and interactions of ash trees and *Hymenoscyphus fraxineus*, the fungus responsible for ash dieback, across Europe with global warming of approximately 2°C and above 4°C at the end of the century<sup>5</sup>, it was projected that by 2050 ash productivity, taking account of the negative impact of *Hymenoscyphus fraxineus*, may increase between 15-50% (Goberville *et al.*, 2016). This was due to the projected higher temperatures encouraging ash growth and dryer summer conditions constraining fungal growth (CCC, 2019b). Crop pests and pathogens have shown an average poleward shift of 2.7+/-0.8 km per year since 1960, consistent with climate change drivers, e.g., warming (Bebber *et al.*, 2013). These trends would be expected to continue with further climate change, leading to more frequent incursions of INNS into the UK, particularly in south-eastern England where average temperatures are warmer and the close proximity to Europe results in some species being introduced by suitable wind patterns (Burgin *et al.*, 2017). Some endemic species that are currently not invasive may become invasive as a result of future climate change. In Wales, invasive species (such as rhododendron) may extend their range to higher elevations in upland western areas due to higher temperatures (Berry *et al.*, 2019). The risk posed by *Dothistroma* needle blight, a major pathogen of Scots pine trees, is also expected to increase under projected climate change, leading to reduced growth and carbon sequestration of Scots pine stands across Wales, northern England and particularly Scotland (Jones *et al.*, 2020).

Uncertainties in species and habitat responses to future climate changes are compounded by large uncertainties in future human interactions, such as biosecurity practices, land-use change, trade patterns and habitat connectivity. Also, the threat posed by cryptic diseases, i.e., those that are difficult to detect (such as phytophthoras) will continue to be difficult to assess. There is much less evidence on the cascade of risks relating future potential climate-pest/pathogen changes to risks for natural terrestrial species and habitats, e.g., relating to key species and their ecosystems (Mitchell *et al.*, 2019). Further details on pests and pathogens of specific relevance to agriculture and forestry are provided in Risk N7 (Risks to agriculture from pests, pathogens and invasive species) and Risk N8 (Risks to forestry from pests, pathogens and invasive species).

### 3.3.1.3 Lock-in and thresholds (N2)

Many pests and pathogens are more difficult and extremely costly to manage once established and widespread across a region (Watkiss *et al.*, 2019). These lock-in risks are often initiated by thresholds (see below), emphasising the importance of enhanced surveillance and other biosecurity measures to facilitate rapid and effective responses and build long-term resilience in native species and habitats. Poor regeneration of key species as a result of pest or pathogen impacts may also risk the sustainability of native species and habitats. For example, the Native Woodland Survey Scotland highlighted the impact of *Dothistroma* needle blight on young Caledonian pine woodlands in Scotland as a factor in the recent poor regeneration levels that threaten sustained woodland growth (Forestry Commission Scotland, 2014).

---

<sup>5</sup> 7 CMIP5 climate models with the RCP2.6 and RCP8.5 concentrations pathways.

Incursions and outbreaks of pests and pathogens are often initiated by the crossing of thresholds, and events. These include human-induced events, such as shipments of infected goods or outbreaks across protected zones, and climate-induced events where pests or pathogens respond to climate variations. For many species, accumulated temperature thresholds regulate the timing of life cycle events and population growth, e.g., Berryman, 1982; Reed *et al.*, 2018. Temperature and photoperiod thresholds are particularly important for the survival and population dynamics of many species, and some, such as mosquitoes and ticks, are also sensitive to moisture availability (Metelmann *et al.*, 2019). Wind speed and direction also exert a major influence on the spread (including incursion into the UK) of some species, e.g., the Diamondback Moth (Wainwright *et al.*, 2020). One of the case studies detailed in a report on climate-driven threshold effects in the natural environment, commissioned by the CCC (Jones *et al.*, 2020), shows that future higher temperatures would be expected to increase incidence of the sheep parasite (*Haemonchus contortus*) across all regions of the UK, with up to 1.6 million lambs affected and estimated annual economic losses of up to £10.2 million depending on the region (see Risk N7 for more details). As climate change progresses, the likelihood of passing climate-related thresholds increases, which would increase the risk magnitude score.

#### 3.3.1.4 Cross-cutting risks and inter-dependencies (N2)

Outbreaks have implications for native species composition and carbon sequestration potential. Changes in trophic level interactions, e.g., predator-prey relationships, affect the resilience of individual species and habitats (Thackeray *et al.*, 2016) and the character and appearance of landscapes. Severe damage or collapse of keystone species may threaten large-scale ecosystems and their services (Mitchell *et al.*, 2019). There are strong interdependencies between trade movements and the risk of incursions and spread. There are also cross-cutting risks and interdependencies across health sectors (plant, animal and human health), such as common vectors for transmission and management approaches. The UK Biological Security Strategy (The Home Office, 2018) highlights that around 60% of all human diseases and 75% of new and emerging infectious diseases are zoonotic (naturally transmitted from other animals to humans), and plant and animal disease outbreaks can have significant effects on the environment and human health.

#### 3.3.1.5 Implications of Net Zero (N2)

The Net Zero target will involve major land-use change, which will affect terrestrial habitats. This will influence the level of risk from pests and pathogens. This will depend on how Net Zero translates into land-use change for managed and unmanaged terrestrial habitats and their subsequent management.

Increases in the abundance of pests or pathogens or in the frequency of outbreaks are likely to reduce plant productivity and divert resources from woodland expansion objectives, making it more difficult to reach Net Zero. This is particularly relevant to woodlands and the forestry sector because woodland expansion and afforestation targets are central to the Net Zero scenario (see Risk N8). Afforestation includes risks from importing tree species and/or planting non-native species, which may introduce or promote the establishment of new pests or pathogens. Also, expansion of wooded areas is likely to increase connectivity of habitats and facilitate the spread of pests and pathogens,

particularly invasive species, across the landscape. In Wales, efforts to reduce emissions from peatlands could be undermined by climate change leading to more effective seedling of Sitka spruce leading to it becoming invasive on adjacent peatlands.

### 3.3.1.6 Inequalities (N2)

There are likely to be inequalities in the risks from pests or pathogens. Proximity to major import locations and/or continental Europe increases the risk from INNS, either as a result of imported goods or incursions from the near continent. Some sectors, habitats and species are also more at risk than others, including agriculture and forestry (see Risks N7 and N8), native woodlands and ash trees (see above on current and future risks).

### 3.3.1.7 Magnitude scores (N2)

**Table 3.5** Magnitude scores for risks to terrestrial species and habitats from pests and pathogens, including Invasive Non-Native Species .

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)
<b>Northern Ireland</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Scotland</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Wales</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)

Notes: Magnitude categories based on the level of agreement of the evidence and expert judgement of authors (in agreement with CCRA reviewers) of medium for the present day with intermediate impacts on or loss of species groups and medium for the future for Northern Ireland, Scotland and

Wales. England is scored as high for the future (major impacts), due to its closer proximity to continental Europe and the higher potential increase in the incursion and establishment of INNS. All countries are high for the 2080s for the pathway to 4°C global warming at the end of the century, due to an increasing risk posed by higher temperatures.

### **3.3.2. Extent to which current adaptation will manage the risk or opportunity (N2)**

#### **3.3.2.1 Effects of current adaptation policy and commitments on current and future risks (N2)**

##### **3.3.2.1.1 UK Wide**

There are a wide range of biosecurity policies and commitments in place to support the management of pest and pathogen risks in the UK. At the international scale, these include multilateral agreements to encourage cooperation and coordination of biosecurity activities among nations and organisations. For example, the International Plant Protection Convention (IPPC) and the World Organisation for Animal Health (OIE) aim to prevent the introduction and spread of plant and animal pests and diseases through development of standards and coordination of biosecurity activities across members. International environmental agreements, such as the UN Convention on Biological Diversity and the Bern Convention, also consider aspects of pest, pathogen and climate change management within the wider context of biodiversity and nature conservation.

Decisions on implementing biosecurity measures in the UK have been made predominantly at EU level, with plant and animal biosecurity in the UK currently following EU legislation. For example, under EU Plant Health Regulations tighter controls have recently been imposed on the import and movement of plants and plant materials in response to heightened risks (House of Lords, 2018). The UK benefits from coordinated EU-wide intelligence gathering, disease notification systems, plant and animal movement tracing systems and coordinated research on pests and pathogens. Post-EU-exit, the UK is no longer automatically part of this framework, and it has been emphasised that continued cooperation and sharing of intelligence between UK and EU are essential to adequately manage the UK's current and future biosecurity risks (House of Lords, 2018).

Within the UK, there is a strong policy framework in place to manage current and future pest and pathogen risks (although our view is that this is less well developed for INNS). This is supported by robust science, including recent recommendations from 'Animal and Plant Health in the UK: Building our science capability report' (GO-Science and Defra, 2014) and subsequent 'Vision and high-level Strategy for UK Animal and Plant Health Research to 2020 and Beyond' (BBSRC, 2016). The UK Biological Security Strategy (HMG, 2018a) also sets out a wide range of activities across Government to protect UK citizens and British interests from significant biological risks, including those posed by pests and pathogens. It also describes four pillars for responding to biological risks: Understand; Prevent; Detect; Respond, which is a good framework for managing pest and pathogen risks in general.

Various approaches are maintained to highlight the ecosystem service value of forest stocks and trees, and therefore provide an indication of the potential losses from pests and pathogens. These include the Office for National Statistics' UK Urban Natural Capital accounts or woodland accounts, Forestry England's annual natural capital accounts, Nature Scotland's national capital accounts, and

the i-Tree Eco tool which has been used in various cities in England, Scotland and Wales to calculate and value the ecological benefits provided by peri-urban/urban trees.

For INNS, the Great Britain Invasive Non-native Species Strategy provides the framework to support coordination of policy and action across England, Scotland and Wales (Defra, Scottish and Welsh Governments, 2015). The Strategy seeks to address the potential damage from INNS through preventing the introduction of such species into the wild, rapid response and early intervention. Defra, Scottish Government and Welsh Government are working with the GB Non-native Species Secretariat to prepare risk assessments and action plans which do include climate change, as well as developing long-term horizon-scanning exercises to identify future threats.

Policies vary by sector, and the agriculture and forestry sectors have a range of policies, commitments and tools to address their specific risks which are detailed in Risks N7 and N8. Adaptation measures also vary significantly for localised or widespread outbreaks. For example, Scotland's forestry and biodiversity sectors now focus on general management strategies rather than control measures to manage the green spruce aphid (*Elatobium abietinum*), which has become widespread across the country (CCC, 2017). Other landowners, including private estates and charities, are developing approaches to manage their specific risks. For example, Historic England have mapped pests and diseases in their historic parks and gardens (Branson *et al.*, 2018) in support of their Climate Change Adaptation Plan. Also, the current status and proposed monitoring and reporting framework has been assessed for managing the threat from pests and diseases on UNESCO World Heritage Sites, historic gardens, houses and museums (Shackleton *et al.*, 2020).

Risk assessment procedures are increasingly important for identifying high-risk species and prioritising actions. For invasive species, the UK Government has put in place both horizon scanning and risk assessment programmes, which enable the identification of emerging threats due to climate change, as well as sleeper species that are already present but could become invasive in a changing climate. For example, the UK Plant Health Risk Register enables stakeholders to identify, prioritise action and evaluate potential adaptive capacity to manage pests and pathogens that threaten UK plant species and habitats. Also, dispersion modelling is used to help assess the risk of spread of some pests and pathogens such as Bluetongue virus (Defra, 2017) or foot and mouth disease (Mikkelsen *et al.*, 2003).

#### 3.3.2.1.2 England

National priorities for action on the environment and climate change are detailed in the Government's 25 Year Environment Plan (25YEP, HMG, 2018b); the overarching strategy for improving the environment in England. The 25YEP includes details on the management and reduction of the impacts of existing plant and animal diseases, reducing the risk of new ones and tackling INNS. It has a goal of enhanced biosecurity with indicators on the abatement of the number of INNS entering and establishing against a baseline and the distribution of INNS and plant pests and diseases, but this is in broader context than just climate change.

The Second National Adaptation Plan (NAP2, Defra, 2018a) included outcomes and goals for managing and reducing the impacts of existing plant and animal diseases, reducing the risk of new ones and tackling INNS. However, it has been noted that neither the 25YEP, NAP2 nor other sector-

specific plans outline measurable targets for managing and reducing the impact of existing plant and animal diseases.

The England Tree Health Resilience Strategy includes provision for assessing the efficacy of planned government action on trees (Defra, 2018c).

### 3.3.2.1.3 Northern Ireland

Northern Ireland has a range of policies for dealing with pests and pathogens (Gioria *et al.*, 2019). An Invasive Alien Species Strategy for Northern Ireland aims to address knowledge and awareness gaps, minimise arrivals and their spread, and eradicate and control INNS (DAERA, 2013). Further policies are in place for specific pests and pathogens, e.g., for ash dieback disease strict policies of eradication and containment are set out in the All-Ireland Chalara Control Strategy which are considered to have significantly prevented the rapid establishment and spread of this pathogen across Ireland (McCracken *et al.*, 2017).

In July 2020, Northern Ireland complied with the EU Regulation (1143/2014) which requires Member States to produce effective management measures for each of the selected Widely Spread Species. These measures will endeavour to minimise the potential negative impact upon biodiversity, related ecosystem services, human health and the economy that these 11 species could have: Nuttall's waterweed (*Elodea nuttallii*); Chilean rhubarb (*Gunnera tinctoria*); Giant hogweed (*Heracleum mantegazzianum*); Floating pennywort (*Hydrocotyle ranunculoides*); Himalayan balsam (*Impatiens glandulifera*); Curly waterweed (*Lagarosiphon major*); American skunk cabbage (*Lysichiton americanus*); Parrot's feather (*Myriophyllum aquaticum*); New Zealand Flatworm (*Arthurdendyus triangulatus*); Grey squirrel (*Sciurus carolinensis*); Slider terrapins (*Trachemys scripta spp.*).

Information on biosecurity risks, legislation and management options for invasive species in Northern Ireland is available *via* the Invasive Species Ireland web site (<https://invasivespeciesireland.com/>), a collaboration between DAERA and the Irish National Parks and Wildlife Service. Also, the Catalogue of pests and pathogens of trees on the island of Ireland provides a valuable baseline on plant pests in Northern Ireland and has been used to study the history of plant pest invasions in Northern Ireland including within the context of climate change (O'Hanlon *et al.*, 2020).

### 3.3.2.1.4 Scotland

The second Scottish Climate Change Adaptation Programme (SCCAP, Scottish Government, 2019) includes references to a National Species Reintroduction Forum project which is working to identify species where conservation translocation could provide various benefits including moving species away from areas of high disease risk (National Species Reintroduction Forum, 2014). SCCAP2 continues to recognise the need to tackle INNS in a variety of habitats and proposes management of INNS as a possible indicator for monitoring non-climate pressures. Prevention, control and eradication of invasive species is a major aim of Scotland's biodiversity policy and the management strategy of protected areas. As part of the Pests and Diseases Research Outcome of SCCAP2, the Plant Health Centre in Scotland have examined the effectiveness of national surveillance monitoring

options for detecting a *Xylella fastidiosa* outbreak (White *et al.*, 2019). Lawrence (2020) notes there are some concerns of over-reliance in Scottish forestry on a small number of tree species which can increase the risk from high impact tree pests or diseases.

#### 3.3.2.1.5 Wales

The latest climate change adaptation plan for Wales 'Prosperity for All: A Climate Conscious Wales' details a range of policy measures to address pest, pathogen and INNS risks (Welsh Government, 2019b).

These include a specific action *to protect our natural habitats from the increasing risks associated with INNS* and sub-actions to: a) implement actions in the GB INNS strategy; b) incorporate biosecurity measures into marine proposals to reduce the risk of introducing and spreading marine INNS; c) coordinate, set priorities and raise awareness of INNS in Wales through the Wales INNS group; and d) introduce contingency plans to respond to newly arrived INNS.

There are also a range of actions relating to tree disease (see Risk N8 for more detail on forestry) including:

- Promote the use of 'i-tree Eco' and similar tools to understand the nature and value of peri-urban/urban trees and assist in pest/disease incidence management.
- Promote resilience to increasing incidence of arboricultural pests and diseases.
- Develop and maintain a risk register of pests and diseases and their threat to tree health in Wales.

Extended surveillance to cover military and civil facilities is also under consideration (Welsh Government, 2019b).

The Invasive Non-native Species Group help identify INNS priorities and resolve issues relevant to Wales. Their members are from Wales Biodiversity Partnership, Academia, GB Non-Native Species Secretariat, Local Authorities, Natural Resources Wales, Public Health Wales, Wales Environment Link, Welsh Government, the Welsh Local Government Association and Utility companies.

#### 3.3.2.2 Effects of non-Government adaptation (N2)

Management of pest and pathogen risk within the UK is strongly coordinated and regulated through government policy, although this is not necessarily the case for INNS (Environmental Audit Committee, 2019). Non-government stakeholders, including farmers, other landowners and nature conservation groups focus on actions relevant to their specific requirements. For example, monitoring individual crops, species and habitats on a day-to-day basis for new pests and diseases, and applying measures to minimise local damage. Increasing diversity is a critical strategy available to non-government stakeholders to increase overall habitat resilience to a wide number of potential risks, as well as delaying or reducing the build-up of pests and diseases within a habitat. Commercial agricultural companies provide a range of tools and advice to support large agricultural organisations and smaller farmers to manage pest and pathogen risks. Advice and guidance on pest

and pathogen risks and management options are also available through trade magazines. For woodland management, interventions that include assisted migration of species from locations with climates closer to the future projections have been suggested, where this is shown to be effective and meet the objectives for the woodland (Forestry Commission, 2020b). There is also potential for 'natural regeneration' approaches to afforestation that reduce reliance on imported samplings and therefore the risk of introducing pests and pathogens.

### 3.3.2.3 Barriers preventing adaptation (N2)

Effective adaptation requires clear understanding of the risks and interactions, available tools and techniques and suitable funding and policy programmes to enable adaptations. The following barriers may prevent appropriate adaptations to pest and pathogen risks from being realised:

- **Research and understanding:** Complexity in the relationships between biotic and abiotic factors influencing pest or pathogen risks can be a barrier to understanding appropriate adaptation measures, and defining measurable goals (CCC, 2019b). Understanding cryptic diseases, i.e., those that are difficult to detect (such as phytophthoras) poses a particular constraint on adaptation actions.
- **Surveillance and inspections:** Adaptation actions may be limited by insufficient inspectors at borders and across the UK and by post-EU-exit restrictions in international collaboration and access to international pest surveillance and early warning data, e.g. the Animal Disease Notification System (ADIS, [https://ec.europa.eu/food/animals/animal-diseases/not-system\\_en](https://ec.europa.eu/food/animals/animal-diseases/not-system_en)). Adaptations for INNS may be particularly limited as there are no existing inspectors for INNS, compared with the established inspectorates for animal, plant, fish and bee health (<https://publications.parliament.uk/pa/cm201919/cmselect/cmenvaud/88/8805.htm>).
- **Funding:** Long-term adaptations e.g., breeding programmes typically have high up-front costs that benefit multiple sectors and stakeholders. It is difficult to quantify the benefit for each sector/stakeholder, which can result in inaction. A recent UK Government Environmental Audit Committee report identified lack of resources as a critical barrier to tackling INNS, noting that only 0.4% of the total annual GB expenditure on biosecurity (approximately £220 million) is spent on INNS. The CCC (2019b) report identified funding and resources as common barriers for adaptation projects in England. They suggest that Government should consider how to de-risk development of funding bids for larger adaptation projects and reduce barriers to accessing such funds.
- **Policies:** Government policies should provide clarity and support for adaptation. Barriers may exist due to inadequate policies and legislation driven in our view by a lack of requirements to include adaptation across the board, and a lack of political leadership to mandate this.

This is also an area where there is a strong justification for Government intervention, especially in terms of legislative control, monitoring and surveillance, and support when outbreaks occur (to minimise spread).

### 3.3.2.4 Adaptation shortfall (N2)

There are risk assessments and a wide range of management measures in place to provide some adaptive capacity to reduce the increasing risks from pests and diseases driven by climate change, but by comparison there are few for INNS in our view, hence our assessment is that the risk is being partially managed across the UK (Table 3.6). There is a compelling need for enhanced monitoring, surveillance and early response measures to prevent a future spread of native pests and pathogens and the establishment of INNS.

### 3.3.2.5 Adaptation Scores (N2)

<b>Table 3.6</b> Adaptation scores for risks to terrestrial species and habitats from pests and pathogens, including Invasive Non-Native Species			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Medium confidence)	Partially (Medium confidence)	Partially (Medium confidence)	Partially (Medium confidence)

### 3.3.3 Benefits of further adaptation action in the next five years (N2)

The economic and environmental costs associated with managing established pests and pathogens are considerably higher than the costs of biosecurity measures to prevent INNS becoming established in the UK (SRUC, 2013). Therefore, further adaptation actions focusing on enhanced prevention (e.g., pathway management), monitoring, surveillance and early response are considered highly beneficial (CCC, 2019b).

Increased horizon scanning for INNS and improved coordination with international pest risk surveillance organisations would help the UK to manage risks associated with changes in the post-EU -exit trade portfolio and projected climate changes. Research since CCRA2 has highlighted various adaptation options and benefits, e.g., in Northern Ireland, recent research recommends that increasing abundance, diversity and care of tree standards in hedgerows would mitigate the impact of tree diseases on the ecosystem services provided by hedgerows on farmland (Spaans *et al.*, 2018).

Further research on the likely responses and resilience of native species and habitats to pest and pathogen risks, and adaptation options to manage these risks, will help inform suitable adaptation decisions. Further research on the implications of projected climate changes within the context of potential changes in trade and other drivers would help understand the primary drivers of future change and plan adaptations appropriately. In general, there is scope for more integrated cross-sector policy initiatives, e.g., across agriculture, forestry, natural environment and human health, to implement good practices and share tools and resources (HMG, 2019; Baylis, 2017).

### 3.3.3.1 Indicative costs and benefits of additional adaptation (N2)

There is a strong economic case for greater Government intervention in research, monitoring, awareness raising and coordination of reactive response to potential and emerging threats (including invasive species) based on case study analysis of four major pests and pathogens *Phytophthora ramorum*, Ash dieback, *Dothistroma* Red needle blight and *Septoria*, a winter wheat yellowing fungus (see Watkiss *et al.*, 2019). Although this would require additional Government action, Watkiss *et al.* (2019) project that the economic benefits are high compared with the costs (at least 10:1). Given reasonable assumptions on the spread of these four diseases, they estimate the additional damage costs (2018 constant prices, discounted) from climate change by 2050 to be increasing by £67.5 million for *Phytophthora ramorum*, £178 to £596 million for Ash dieback, £300 million for *Dothistroma* and decreasing by £83 to 245 million for *Septoria*.

There is a clear a role for public co-ordination of research, monitoring and surveillance. Previous analysis by SRUC (2013) has identified that investment in monitoring for pests has a high benefit-cost ratio of around 10:1. There are also clear benefits from Government investing in information about pests and pathogens – their spread, likely impacts, and treatment methods – as this information flow would not otherwise occur. Whilst a large proportion of the costs (or pests and pathogens) may be borne by private land-owners, public support is likely to be needed where there are local concentrations of economic activity that are threatened by the rapid spread of one of these pathogens in an area (to reduce the much larger costs once pests and pathogens become established). This economic argument is strengthened by climate change because the future nature of the threats will be less understood by private actors' past experience.

### 3.3.3.2 Overall urgency scores (N2)

<b>Table 3.7</b> Urgency scores for risks to terrestrial species and habitats from pests and pathogens, including Invasive Non-Native Species.				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Medium	Medium	Medium	Medium

Because the magnitude of future risks is high for all countries in the 2080s under a 4°C world, and the view that current adaptation plans will only partially manage the risk, additional intervention is needed to better manage future potential impacts, this risk has been scored as more action needed.

### 3.3.4. Looking ahead (N2)

Enhanced monitoring, surveillance and early response measures are needed to manage the risk to UK terrestrial species and habitats from pests and pathogens, especially in view of the need for improved international coordination following EU-exit. Regulations and resources will need to keep pace with the increasing risks and management measures required and consider the changing

portfolio of risks e.g., from INNS relative to native species. A range of interventions are available to manage future climate change risks to species and habitats, including assisted migration and increasing diversity. Management actions need to be supported by biosecurity strategies and policies that improve protection from high-risk activities, including plant sales, aquaculture, transport of live animals and plants and their products. Further research is required to understand specific climate responses and thresholds of high-risk pest and pathogen species, and the potential change in risk associated with different adaptation options. UK mapping of multiple pest and pathogen observations would support communications on risk across administrations and organisations within the UK. There is also scope for improved collaboration across biosecurity sectors (plant health, animal health, human health and INNS) and with relevant disciplines e.g., meteorology (Hemming and MacNeill, 2020), providing increased capability and resource sharing.

### 3.4. Opportunities from new species in terrestrial habitats colonisations (N3)

- Opportunities are unlikely to be fully identified currently, as some classes of organisms are more studied and visible (e.g., birds).
- Whilst species may have suitable climate space, they may not have moved into it yet due to their lack of mobility (adaptive capability) or the absence of other requirements.
- Current and future opportunity is assessed by experts as medium but increasing to high for a pathway to 4°C global warming at the end of the century, as there are greater opportunities for range expansion.
- Further investigation is needed to identify species for which climate change would represent an opportunity and to understand the implications of their arrival into new areas or habitats, whilst considering how to integrate them into future conservation planning.

#### Introduction

CCRA2 assessed the opportunities from new species colonisations (CCRA2 Risk Ne2), concluding that more action was needed in terms of building coherent ecological networks and factoring climate change into conservation planning. As identified in Risk N1, while a number of terrestrial species and habitats are at risk from climate change, there are those that could benefit. Opportunities of climate change will be taxon and species specific, with more mobile species likely to be more responsive. Climate change, especially increasing temperatures, can provide the opportunity for increases in populations, as well as leading to species moving and / or expanding their ranges northwards or to higher altitudes. Thus, they have the opportunity to colonise new areas. This can take two forms, firstly the species can be new to Great Britain or Ireland, although the level of migration is restricted as both are islands. Secondly, the species may be new to a UK country or region. If the new species interacts negatively with native species, or alters habitat condition, then it is considered an INNS or pest (Risk N2). In more positive cases, new species can enhance species richness and contribute to community adaptation to climate change. Also, while both of these can be consistent with climate change, often it is a complex situation involving other drivers. There is also the possibility of migrant

species becoming resident in an area, thus enhancing its biodiversity, providing they do not negatively compete with native species, for example, for limited winter food supplies.

### 3.4.1 Current and future level of opportunity (N3)

Note: currently available evidence is not sufficient to allow us to report on the current and future level of opportunity, for each UK country separately.

#### 3.4.1.1 Current opportunity (N3)

New species are migrating into the UK (Hubble, 2014; Gurney, 2015) and, while it is often consistent with climate change, especially if they have come from the continent, it is often difficult to attribute this to climate change, with humans more often implicated in the arrival of new species. Given suitable habitat, it is likely that they will expand their range and there is potential for them to become invasive (see Risk N2).

While there is a mixed response to climate change within and across taxa, some, such as mammals show an overall net positive response (Burns *et al.*, 2016). This may be dependent on factors such as geography, ecology of the species and habitat changes, but the threat posed by climate change to many species (Risk N1) should not be underplayed. Analysis of northern range margin changes of 1573 southerly-distributed species from 21 animal groups in Great Britain over the past four decades found that, while most ranges shifted northwards in both the two time periods, some (e.g., macromoths) shifted southwards in one of the time periods (Mason *et al.*, 2015). In the more recent time period, macromoths and butterflies have moved north faster. While Fox *et al.* (2014) found an overall decrease in frequency of occurrence across 673 macromoth species in Great Britain, 160 species, mostly in southern Britain, showed an increase consistent with climate change. A decrease in overall moth abundance (based on 176 species) similarly was found for Scotland, but estimated population trends were positive for 29% of species (Dennis *et al.*, 2019). An occupancy indicator (based on 230 species) showed a 16% increase for 1990–2014. In both cases climate change was suggested as a possible driver, although for some moth species, especially those that use conifer woodlands, changes in land use and management may have contributed to their positive response.

An assessment of latitudinal and elevational shifts in range margins of 80 breeding bird populations in Great Britain between 1994–2009, showed poleward shifts in the leading (northern) range margin were greater than those of the range-centre, while the trailing range (southern) margin was largely static (Massimino *et al.*, 2015). Thus, there was significant range expansion, with the expansion lagging behind the changes in temperatures. The results held even for (rarer) species for whom range contraction might be expected. A mixed response was found to change in elevation. Gillings *et al.* (2015) analysed the range shifts of the distributions of 122 species of British breeding birds during 1988–1991 and 2008–2011 and a full range of directional axes. They estimated a 13.5 km shift northwards had occurred, but that the directions of species' range centroid shift were not correlated with spatial trends in any single climate variable. This suggests that range shifts of British birds are multidirectional, individualistic and probably determined by species-specific interactions of multiple climate factors, with a consequence for change in community composition.

A literature and expert-based review of the drivers of change across 322 species sampled from a broad range of taxonomic groups in the UK found that increasing climate change was the most positive driver species population changes (~1970–2012) for invertebrates and vertebrates (Burns *et al.*, 2016). Many mobile species with southern distributions are increasing and colonising new areas. In the case of once rare species, such as the Dartford warbler, it continues to be limited by cold winters (Bradbury *et al.*, 2011), most recently in 2009/10, it is increasing in numbers and expanding its range (Green, 2017). This is attributed to milder winters (Hayhow *et al.*, 2017). Resident species, such as great tits, robins, dunnocks and wrens, also seem to be benefitting from the warmer winters and springs. Milder winters are also leading to increased populations of short-distance migrants, such as chiff chaffs and blackcaps and to the expansion of their range northwards and to higher altitudes.

Butterflies and moths have been shown to respond more to changes in seasonal temperatures, with the spatial variation in the community composition of moths being associated with winter and summer temperatures and butterflies with winter and autumn temperatures (Martay *et al.*, 2016). As seen for other taxa, current increases in these seasonal temperatures will have benefited certain species.

The expansion of some rare species also has been postulated to be associated with climate change (e.g., ambrosia beetle in the Wye Valley SAC; Alexander, 2019), whilst the increase of some bryophytes in Wales have been associated with decreased sulphur dioxide pollution combined with climate change (Motley and Bosanquet, 2017).

Species will not only be affected by mean or seasonal climate changes, but also by extreme climatic events. These can lead to a population explosion, which may lead to positive long-term population trends in birds, although no evidence was found for butterflies and moths (Palmer *et al.*, 2017). Climate, however, is only one of a number of interacting factors that will affect the ability of species to realise the opportunity presented by increased suitable climate space. Platts *et al.* (2019) found that in Great Britain, across 13 invertebrate taxa, up to half of the observed variation in rates of range margin shift) between 1976–1990 and 2001–2015 could be explained by habitat-climate interactions, with habitat availability constraining climate driven range margins shifts. While an analysis of the roles of abundance trends, habitat availability and dispersal capacity in the range changes of 25 British southerly distributed butterfly species during two periods found that for species with stable abundances whose ranges are already expanding, management such as habitat restoration/creation may increase their rates of expansion (Mair *et al.*, 2014). However, for species with declining abundances, management to stabilise and increase abundance trends within the core of species' ranges is required first.

Thus, a number of opportunities across a range of taxa have been identified of species expanding their range and population numbers, which are, at least partly, driven by climate. Species arriving in Great Britain are likely to have come from the continent, and, based on evidence for Invasive Non-native Species they are more likely to arrive in southern Britain (Gallardo and Aldridge, 2013; 2015). For species expanding their range polewards in Great Britain, they will progressively move

northwards, reaching Scotland if suitable climate space and other factors permit. The same would apply for the Republic of Ireland and Northern Ireland. The situation for Wales is less clear. Population changes are likely to be more species specific, although Hayhow *et al.* (2017) showed that increases in populations of some resident birds (e.g., great tits, robins, dunnocks and wrens) have been greatest in Northern Ireland, followed by Scotland, with no significant difference in England and Wales. This is thought to be due to improving climatic conditions in the north and west.

#### 3.4.1.2 Future opportunity (N3)

Based on what is currently happening, it is likely that climate change will continue to offer opportunities to some, especially mobile, species, which have suitable habitats and food sources in their potential new climate space. However, some will not be able to fulfil their dispersal potential for a number of reasons, including lack of a supply of migrants, dispersal routes and suitable habitat availability (Mair *et al.*, 2014). Modelling undertaken for CCRA2 projected a potential for new suitable climate space under 2°C and 4°C scenarios for many species in the UK, especially in northern England and Scotland. This is largely a result of warmer mean temperatures. Recent publications are consistent with this. For example, a simple analysis (based solely on climate) of 3048 species from a range of taxa, compared projected future distributional changes with recently observed changes and found that, under a scenario of 3°C global warming by 2100<sup>6</sup>, climate change could represent a medium or high opportunity for 54% of species in Great Britain through increased suitable climate space (Pearce-Higgins *et al.*, 2017). The taxonomic variation in the proportion of species with opportunities varied from 37% for bryophytes to 90% for wasps. An association of species with habitats indicated that the opportunities were evenly distributed, apart from upland, where risks substantially outweighed the opportunities. A more comprehensive analysis of 402 species that took into account some of the other factors that affect species' distributions and response, showed that a scenario of 3°C warming by 2100 could represent an opportunity for 42% of them, with ants and wasps potentially benefiting the most (Pearce-Higgins *et al.*, 2017). The study concluded that climate change appears to represent an opportunity for more species than a risk, as more species are at their northern range margins in Britain than at their southern range margin. However, there is evidence that as richness increases homogenisation of communities may occur due to the spread of more generalist species and the decline of more specialist ones (Platts *et al.*, 2019; Harrison, 2020). Also, as already identified, climate is only one factor that affects species response to climate change.

Modelling of changes in suitable climate for birds under the future 3°C warming scenario projected that some birds (such as melodious warbler, short-toed eagle, red-backed shrike, short-toed tree creeper) potentially could establish (or re-establish) regular breeding populations in Britain in the next few decades at least partly as a function of climate (Ausden *et al.*, 2015; Hayhow *et al.*, 2017). For some, this will be moderated by habitat availability or adverse impacts of climate change on the habitat. Massimino *et al.* (2015) modelling changes in climate suitability for 124 bird species in Great Britain with a scenario of approximately 4°C global warming by 2100<sup>7</sup> also suggested it could increase for 44% of species by 2080, with 15% of species projected to increase by 2080 currently red-listed (high conservation concern) and 13% amber-listed (medium conservation concern). The largest increases were projected for the north and west, especially in Scotland, whilst declines in

---

<sup>6</sup> UKCP09 probabilistic projections with the low (SRES B1) scenario

<sup>7</sup> UKCP09 spatially coherent projections with the SRES A1B scenario

red-listed species were widespread, but with gains in Scotland. Thus, turnover is also higher in the west of Britain due to large changes in species already present (see Figure 3.5 and Figure 3.6 in Risk N1).

Some opportunities identified for Welsh landscapes include warmer mean temperatures lengthening the growing season and enabling trees, grasses and shrubby plants to grow at higher elevations, resulting in a raising of the moorland line (Berry *et al.*, 2019). This could lead to the expansion of grazing and an increase in grassland productivity, but this could be at the expense of semi-natural habitats, such as upland heath. Broadleaved tree species are likely to be more widespread in central and eastern Wales, which could present an opportunity for increased timber production, carbon sequestration and woodland habitat expansion for conservation.

#### 3.4.1.3 Lock-in and thresholds (N3)

The arrival of new species may not be taken into account in protected site designations and boundaries and thus lead to uncertainty about their condition for conservation. It may take time for the necessary changes to be made.

Each species has bioclimatic constraints, but in the case of opportunities these are unlikely to be reached, unless extreme events cause local extirpations. The benefits are likely to increase with the higher emissions scenarios and over time, providing a critical upper threshold is not reached.

#### 3.4.1.4 Cross-cutting risks and inter-dependencies (N3)

New terrestrial species, either arriving from the continent or migrating from southern areas, might have the potential to become invasive. If they are invasive then it is highly likely that they will negatively impact native biodiversity, in which case they would come under Risk N2. However, for colonisation and migration these species will require suitable habitat/host species, which may not be present, particularly for colonisations in southern England from continental Europe.

Management of flood risks could affect the habitat availability and/or connectivity, with nature-based solutions and natural flood management potentially enhancing the realisation of the opportunities for species.

#### 3.4.1.5 Implications of Net Zero (N3)

This opportunity is unlikely to affect the achievement of the Net Zero target, but the migration of species could be enhanced by the associated afforestation and peatland restoration measures and the changes in agriculture practices leading to the provision of more and/or better habitat. These, combined with actions to increase habitat connectivity, including hedgerow planting, and buffer strips could increase rates of species colonisation for species of limited mobility. Also, it could provide an opportunity for planting new, climate adapted species. For tree planting, this would depend on where and how it is carried out; semi-natural woodland with a mixture of native species will benefit more species than monocultures and non-native species, which could result in the fragmentation of native habitats. There is a possible increased threat to certain habitats from bioenergy.

## 3.4.1.6 Inequalities (N3)

No inequalities were identified in relation to opportunities to terrestrial species and habitats from climate change.

## 3.4.1.7 Magnitude scores (N3)

<b>Table 3.8</b> Magnitude scores for opportunities from new species in terrestrial habitats colonisations .					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Northern Ireland</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Scotland</b>	Medium (High confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Wales</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)

Notes: Magnitude categories based on some independent evidence and the expert judgement of authors (in agreement with CCRA reviewers) of medium for the present day and, therefore, likely medium magnitude of opportunities for species groups (category: 'Intermediate opportunities for species groups') but increasing to high for 4°C world as there are greater opportunities for range expansion.

### 3.4.2. Extent to which current adaptation will manage the opportunity (N3)

#### 3.4.2.1 Effects of current adaptation policy and commitments on current and future risks (N3)

The adaptation policies and actions relevant to reversing declining trends in native species (see Risk N1) are also applicable to facilitating the realisation of climate change driven opportunities for expansion. To avoid repetition, they will not be covered here. New species and the realisation of opportunities are not (often) specific components of such adaptation plans, but they are likely to be beneficially affected by them. For example, protected areas (Sites of Special Scientific Interest) have been found to be effective for a selection of birds and butterflies expanding their range margins (Gillingham *et al.*, 2015). Habitat loss and fragmentation are important factors affecting the opportunity for species expansion to be realised. So, actions which create new habitat, either through expanding existing sites or creating new ones, or increase the connectivity between habitats (e.g., through Nature Recovery Networks) can help species to colonise new areas. Managing sites better to improve their condition can also help them to support larger numbers of species and facilitate colonisations.

Despite this, in our view there are many species of low mobility that are unlikely to be able to colonise new sites on a fast enough timescale without direct, targeted interventions (Ellis, 2015; Schloss *et al.*, 2012) including deliberate translocation, for which there is no current scheme or support across the UK, as yet. There is, therefore, an adaptation shortfall, with resources needed to facilitate the movement of species, particularly natives, whose suitable climate space is moving northwards, through, for example, more dynamic site management and planning, adaptation-related objective setting and condition assessment and targeted adaptation interventions. These should work alongside existing and planned strategies and measures (see Risk N1), which if met, could make significant steps in enabling species to migrate in response to climate change, for example through halting and reversing habitat degradation and fragmentation of the natural environment. In Scotland, a National Species Reintroduction Forum project (led by NatureScot and Royal Botanic Garden Edinburgh) is working to identify species where assisted colonisation and other forms of conservation translocation could benefit species at risk from climate change, alongside wider environmental benefits.

It will also be necessary to ensure that management plans, objectives and condition assessments of protected sites take account of new species colonisations to ensure management that supports colonisations (or in the case of invasive species, pests or diseases, prevents them), as mentioned in N1. Evidence and advice are essential to make informed decisions about these issues, and there is a lack of evidence to show that this is yet happening.

It is unlikely that EU-exit or Covid-19 will have any significant effect on the realisation of the opportunities.

### 3.4.2.2 Effects of non-Government adaptation (N3)

As highlighted above, species migration will enable some of these opportunities naturally, provided there is suitable habitat. There is unlikely to be private sector (e.g., landowners) adaptation action to facilitate these opportunities in the absence of Government action, unless they are associated with financial benefits.

Our view is that adaptation actions can happen locally on a small scale through NGOs, individual and community group initiatives, however large-scale habitat creation and improvement usually depends on government action and often are supported by government funding, such as agri-environment schemes.

The shortfall in adaptation will not be addressed by non-government adaptation alone therefore, as while many environmental NGOs and private landowners are involved in delivering adaptation measures at specific sites, generally there is not an integrated approach or a sufficiently widespread take up of appropriate actions to reduce future risk down to low levels. Contributing to the development of the ecological networks would be a useful non-governmental contribution.

### 3.4.2.3 Barriers preventing adaptation (N3)

Habitat availability, fragmentation and slow dispersal rates present challenges for species colonising new sites. The first two can be addressed by habitat restoration, re-creation and improved connectivity in areas where this is lacking for particular species. Translocation to newly available suitable sites is an option but is often considered as a last resort option because it is resource intensive and even when all the background factors are favourable, both biophysical and socioeconomic (notably land management), there is no guarantee of long-term success. Nevertheless, despite these challenges, there are now initiatives to further investigate this option with regard to newly available sites, such as the National Species Reintroduction Forum project mentioned above for Scotland.

### 3.4.2.4 Adaptation shortfall (N3)

Intervention, through actively supporting new species' colonisations, is likely to be required to realise this potential benefit in full. While general policies and programmes to improve habitat condition, extent and connectivity (see risk N1) will have known benefits for supporting species expansions and new species introductions, as stated above there are no current programmes that we are aware of that specifically support new colonisations or translocations, though work is underway (e.g. in Scotland) to assess which species could benefit from such schemes. As such, our assessment is that this opportunity is only being partially managed.

## 3.4.2.5 Adaptation Scores (N3)

<b>Table 3.9 Opportunities from new species in terrestrial habitats colonisations</b>			
<b>Are the opportunities going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
No (Low confidence)	No (Low confidence)	No (Low confidence)	No (Low confidence)

## 3.4.3 Benefits of further adaptation action in the next five years (N3)

At the time of writing, it is not possible to assess the extent of the impact that many new strategies and policy initiatives will have on adaptation, but they have the potential to be important in terms of habitat creation, restoration and connectivity. This may be further enhanced by carbon offsetting and government funding in support of Net Zero, such as through the Nature for Climate Fund. There are, however, risks, from intensive forestry and biofuel production if carbon sequestration alone is a driver. A key adaptation action that would have benefits in the next five years is to ensure join up with Net Zero mitigation policies. Other possible funding opportunities include the Government's Investment Readiness Fund (IRF) which will support the development of natural environment projects that can generate revenue from ecosystem services and attract repayable investment but could include nature-based solutions for climate adaptation and mitigation.

## 3.4.3.1 Indicative costs and benefits of additional adaptation (N3)

As highlighted above, the potential size of the opportunities involved are not well characterised, and this makes it difficult to assess the potential costs and benefits of adaptation: a low regret option would therefore be to investigate these potential opportunities, and to consider what steps might be needed to help realise the most important.

## 3.4.3.2. Overall urgency scores (N3)

<b>Table 3.10 Urgency scores for opportunities from new species in terrestrial habitats colonisations</b>				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency Score</b>	Further investigation	Further investigation	Further investigation	Further investigation
<b>Confidence</b>	Low	Low	Low	Low

This opportunity has been scored as Further Investigation due to the low evidence of the long-term effects of new species movements into the UK, together with a lack of understanding of which specific policies would have most benefit in realising the opportunities from climate change driven

arrivals of new species in terrestrial habitats. Some research is already underway in Scotland, but this could be expanded across the UK and reflected in upcoming national adaptation programmes.

#### 3.4.4 Looking ahead (N3)

In the future, it will still be necessary to develop new approaches to establishing species in new locations and adapting conservation objectives setting and condition assessments to reflect changing distributions, for which there are no specific current plans or funding. It would also be good to consider a more systemic approach to managing biodiversity, so that opportunities can contribute to a more climate resilient future.

### 3.5. Risks to soils from changing climatic conditions, including seasonal aridity and wetness (N4)

- There is increasing evidence of the negative impacts of climate change on soil resources, often in combination with other factors (notably land use)
- Future climate projections, including UKCP18, provide strong evidence that climate risk factors will increase, including due to heavier rainfall events (erosion and compaction risks), and increased soil moisture deficits in summer (loss of biota and organic matter etc.)
- Loss of soil resources has important environmental, economic and social consequences and severe degradation of soil quality would be very likely to have long-term, potentially irreversible, implications.
- There is an urgent need for further research and comprehensive monitoring of soils to support development of sustainable soil policy initiatives.
- While there is an increased awareness of this threat, a significant shortfall remains in the adaptation responses, which are not yet commensurate with this risk level.
- Risks to soils are scored with a More Action Required category, with the magnitude of risk increasing from medium at present to high in future.

#### Introduction

As with CCRA2, risks to soils are identified as requiring more action. The magnitude of risk increases from medium at present to high in future, and, although awareness of this threat has improved, the necessary adaptation responses are not yet commensurate with this level of risk. In making this assessment, although we provide supporting quantitative evidence of the risks to key soil functions and services where possible, we have more generally applied expert opinion to distinguish the many direct and indirect effects of climate change from other drivers.

Soil health is crucial for the terrestrial natural environment. In addition to their importance for maintaining biodiversity (Risk N1 and Risk N3), soil provides multiple ecosystem services, notably for agricultural and forestry production (Risk N6 and Risk N9) for which soil fertility is extremely important, but also equally importantly in terms of regulating water flows and water quality,

recycling nutrients, and carbon storage (Risk N5), together with many other benefits including for landscape character (Risk N18) and cultural value (including archaeology).

A further crucial issue is the need for more research and monitoring of soils to support development of sustainable soil policy initiatives. The UK has over 700 soil types and many variations within those types. Soils are complex systems integrating biological, chemical and physical processes that are sensitive to climate change and other factors such as land management and pollution. Our knowledge of these processes in a changing climate and the implications for key soil properties remains a basic constraint. In particular, improved knowledge of the controlling properties and processes that regulate change (e.g., organic matter, microbial activity) would be extremely useful. In addition, measured or modelled changes in the reciprocal relationships between soil microbial communities and plant communities and their traits (Risk N1) across a range of ecosystems would be advantageous for improved understanding of changes in ecosystem functioning and regulating ecosystem services.

Regarding interactions of this risk with the co-evolving challenges of EU-exit and Covid-19, there is currently an absence of evidence. EU-exit will have an influence through its relationship with land use patterns, especially for agriculture (e.g., trade agreements; regulatory frameworks), and their impact on soils, positive or negative. For Covid-19 it is too early to infer consequences but there is some evidence that soil fieldwork including sampling and monitoring initiatives has been delayed.

### 3.5.1 Current and future level of risk (N4)

#### 3.5.1.1 Current risk (N4)

CCRA2 identified that the risk to the soil resource was severe and increasing, with more action needed to reduce existing pressures on soils and better respond to climate change through proactive conservation of soil resources. We now re-assess that previous analysis in the light of new evidence. However, limitations regarding current soil sampling monitoring relative to the inherent spatial and temporal variability of soil properties and processes act to constrain confidence in knowledge of existing risks, meaning there is a possibility that risk magnitude could be higher than identified.

Climate parameters influencing soils include temperature (notably through its influence on soil temperature and net primary productivity); precipitation and evapotranspiration which influence soil moisture, water leaching etc.; and wind which can interact with specific soil textures. These parameters interact at different scales, and also with other influences such as parent material, topography, fauna, and flora, meaning soils can be complex and vary over small spaces, even at field level. Land use and land management also varies with soil type which over time can cause further variations in soil types.

As identified by CCRA2, there are notable difficulties in distinguishing climate change from other factors, and also differentiating climate change trends from background climate variability (especially in terms of the influence of precipitation). For this reason, evidence for some risks to soil health has no clear consensus, although this can also be related to methodological differences. A further challenge for soils is that the current generation of land surface models used for climate change assessments have limitations regarding the crucial role of biophysical feedbacks in changing soil moisture and soil hydraulic functions (Robinson *et al.*, 2019).

In addition, many risks to soils are the product of climate-related processes acting together with socioeconomic factors to cause soil degradation, notably land use and land management, therefore also contributing to long-term degradation of the land resource. A simple attribution of specific effects to climate as distinct from other factors is therefore probably unrealistic, not least due to the challenges of generalising from limited sample data. Recent soil status assessments reaffirm that generally UK soils are not in a sustainable condition (Natural Resources Wales, 2016; Climate Change Committee, 2018; EA, 2019a; Royal Society, 2020). Soil degradation has occurred from erosion (water and wind), compaction, modification of water-holding properties notably by drainage, loss of soil organic matter (and soil organic carbon SOC), loss or modification to soil biodiversity, imbalance of nutrients, release of legacy contaminants into water bodies, and soil sealing. Climate change potentially could have some benefits for soils through enhanced net primary productivity (from temperature increases and elevated CO<sub>2</sub>) and increased organic matter, but this will also be affected by temperature-related changes in decomposition rates: evidence here remains equivocal as discussed further for Risk N5.

As summarised below, available evidence suggests aggregated climate-related pressures (direct or indirect) cover a significant proportion of the UK soils resource, with major implications for ecosystem services that soils provide. Nevertheless, the sparsity of large-scale soil monitoring data limits our understanding of current trends in climate-related pressures. Natural England's Long-term Monitoring Network (LTMN) is currently the only ongoing long-term sampling programme assessing soils in the UK and this is concentrated on semi-natural habitats in England rather than the broader range of land uses that would include agricultural, afforested or urban environments. This LTMN has recently completed a baseline assessment which provides data on spatial variations in soil properties as a precursor for further work on trend analysis (Natural England, 2017). In Wales, the Glastir Monitoring and Evaluation Programme (GMEP: Emmett *et al.*, 2017) has used 4 indicators of soil quality to summarise progress on land used for agri-environment schemes, finding an improving long-term trend on almost 50% of this land, with 10% a declining trend (remainder not changed).

Regarding soil compaction, recent assessment affirms that this has a serious detrimental effect on soil structure for a significantly large area of the UK, also affecting crop rooting and productivity, decreasing infiltration rates (therefore affecting flood risk and water quality through increased runoff), and increasing N<sub>2</sub>O emissions (Royal Society, 2020). An estimated 3.9 million ha of agricultural land have been identified at risk of compaction in England and Wales, with the risk highest on clay soils during wet periods and for arable land. This large area at risk means that the total cost of compaction has been previously estimated at £472 million/yr (nearly 3 times greater than estimated for erosion) using a methodology based upon dominant soils/land use combinations ('soilscapes') and valuation of final ecosystem goods (Graves *et al.*, 2015). Loss of soil macropores have been identified as especially critical in increasing surface runoff response which climate change may be exacerbating through increased rainfall rates (Alaoui *et al.*, 2018). In Scotland, areas of intrinsic compaction risk have been mapped with a focus on the main agricultural areas (Lilly and Baggaley, 2018), although it is not known with certainty the full extent of compaction within this risk area. Analysis in Wales has indicated that catchment-wide soil structural degradation is estimated to result in a 10 to 20% reduction in soil water storage capacity, and to contribute up to a 10% increase in short term river flow response to rainfall during the field capacity period (Anthony, 2019). In some catchments, soil degradation in combination with changing rainfall patterns (notably greater

intensity) can therefore be a significant factor contributing to increased flood risk, although this will also obviously be influenced by other catchment properties.

In England and Wales, it has been previously estimated that 2.2Mt of soil is eroded each year (EA, 2007). A more recent estimate has suggested a similar soil loss of 2.9Mt/yr with associated productivity losses estimated at ca. £40 million/year, and total costs from decreased soil and water quality at ca.£150 million/year (Graves *et al.*, 2015 using the same soilscales and ecosystem goods methodology referred to above). In Scotland, the total costs of soil erosion by water (including in downstream locations) when extrapolated from 5 case study catchments have been estimated at £31-50 million/yr, with the upper end of the range including drinking water treatment (Rickson *et al.*, 2019). Erosion rates typically vary from <1 to 20 Mg/ha/yr (Defra, 2009), with the higher rates being considerably in excess of soil formation (typically 0.3-1.4Mg/ha/yr) and hence causing severe loss of the soil resource. A recent compilation of UK soil erosion data has suggested that 16% of observations on arable land were greater than the supposedly tolerable rate of 1 t/ha/yr and maximum erosion rates were as high as 91.7 t/ha/yr, although the database probably contains a bias towards locations with a known erosion likelihood (Benaud *et al.*, 2020).

Evidence is increasing that in agricultural areas, degraded soil structure and ineffective artificial drainage may be notable contributors to increased flood risk and poor water quality, although this evidence is mainly from specific catchments rather than a large-scale survey. Analysis in 4 Scottish catchments following the extremely wet winter of 2015/16 by Hallet *et al.* (2016) using a sample of 120 fields found a 30% increase in occurrence of severely degraded topsoils compared to the situation before. Run-off, erosion, and nutrient losses increased by about 10 times in the most degraded parts of the fields (tramlines etc.) and a simple model suggested some agreement between structurally degraded areas and those ranked as being susceptible to topsoil compaction.

Drained and cultivated lowland peatlands are identified as notably vulnerable to climate change, as they currently lose about 1-2cm of soil depth every year due to oxidation and erosion, with the loss of soil carbon reducing soil fertility and contributing ca. 7 MtCO<sub>2</sub>e/yr to UK GHG emissions (Environment Audit Committee, 2016; Office for National Statistics, 2019. Observed increases in rainfall intensity shown by the UKCP18 study of current climate trends imply increased soil erosivity and soil losses to water erosion, as found by analysis of recent data for south-east England (Burt *et al.*, 2016). Increased soil erosion risk is especially present on land uses (notably arable) that involve bare ground at sensitive times of the year unless precautionary management practices are in place.

Implications of current climate change for losses of soil organic carbon are specifically addressed in Risk N5. Again, as identified by CCRA2, the complexity of soils in terms of spatial and temporal variations, notably lagged effects and ongoing adjustments towards an equilibrium with climate, land use and other drivers, mean there continues to be considerable uncertainty at UK scale. Graves *et al.* (2015) estimated the total organic carbon loss in England and Wales to be 5.3 Mt/yr from all drivers and equated this with annual costs of £3.5 million/yr from impacts on agricultural productivity and £566 million/yr from excess carbon emissions (using soilscales and ecosystem goods methodology referred to above).

Regarding the impact of wildfires on soils, evidence suggests damage occurs from hotter, more intense fires that spread heat to the substrate (Belcher *et al.*, 2021). In the UK, fire frequency remains episodic making a climate-related trend difficult to detect but occasional larger fires occur in

dry conditions during spring and summer which can become especially extensive and longer-lasting on peat soils causing substantial soil damage, biodiversity loss and carbon emissions (see Risk N5).

CCRA2 extensively reviewed evidence for the impact of climate change on soil biodiversity and soil composition, including implications for ecosystem functions. The direct and indirect effects of temperature and moisture changes vary across differing soil types and their associated land uses which makes generalisations difficult, but key functional groups, notably the changing status of decomposer, has been identified (Classen *et al.*, 2015). An additional risk factor is the introduction of invasive species with their establishment and spread encouraged by climate change. For example, it has been suggested that introduction of the New Zealand flatworm may have reduced earthworm biomass by 20% (Murchie *et al.*, 2013), with resulting implications for soil structure and functioning because of earthworms' key role as ecosystem engineers. Earthworm presence in agricultural soil has been associated with a 25% increase in crop yield and a 23% increase in above-ground biodiversity (van Groenigen *et al.*, 2015).

Climate change can influence soil microorganisms directly and quite rapidly by altering their growth and activity, but also by indirect effects through plant-soil interactions, but we continue to have limited evidence on these changing feedbacks. Interaction can therefore occur through shifts in plant communities and vegetation (including litter quality and water-use efficiency), which modifies resource availability for soil microorganisms. Similarly, plant growth is also strongly influenced by the soil microbial community that provides nutrients through mineralization of organic matter. The limited evidence on these feedbacks should be a major source of concern because this reciprocal relationship underpins ecosystem function and resilience, hence regulating ecosystem services (including water and soil purification) that then also maintain delivery of other ecosystem services (provisioning and cultural).

Finally, it should be noted that some soils are primarily the products of past industrial activities that have left a legacy in terms of release of unconsolidated material from contaminated land, spoil tips, and mine tailings. These have always been vulnerable to reactivation, especially during extreme weather events, most notably heavy rain. However, the current trend towards increased frequency and magnitude of intense rainfall events (see Chapter 1: Slingo, 2021) indicates a further elevation of risk for this hazard, especially for former mining areas. Recent awareness of this risk has been most pronounced in Wales, where 40 old spoil tips have been assigned to the high-risk category whilst over 9000 contaminated sites have yet to be fully investigated (see Chapter 4: Jaroszweski, Wood and Chapman, 2021 for more details). Heavy rain during early 2020 caused a large landslide on one of these sites at Tylorstown in the Rhondda valley. It is quite likely that other former mining locations throughout the UK also have changing risk profiles due to changing climate factors but at present evidence on this change in risk is rather limited. Around 300,000ha of UK soil are thought to be affected by the legacy of industrial contamination (Environment Audit Committee, 2016).

#### 3.5.1.2 Future risk (N4)

As detailed below, our interpretation of the available evidence suggests that the climate sensitivity of soils together with their current status, which is often in poor condition, would mean that future climate change would significantly increase aggregated risks to soils and their functions or services. This inference is largely based upon extrapolation of current trends and limited modelling and field experiments, which are usually derived from specific soil types or locations, hence confidence

remains low. In addition, our assessment implies that there is the potential for major threshold effects which will become more likely at higher magnitudes of climate change (e.g., +4°C scenarios). It is also important to highlight the expected strong interaction with future change in socioeconomic drivers, notably land use and the continuing effects of atmospheric or other pollutants, although research on these interactions is also limited.

In addition to the expected effects of temperature increases on biological, chemical and physical processes, soils will also be strongly affected by seasonal changes in soil moisture, and for some soil types this may be even more of a critical risk factor. In this context, UKCP18 projections that suggest increasing soil moisture deficits over much of the UK and for most of the year are likely to have profound implications, including changing the relative rate of soil aerobic against anaerobic microbial activity, together with water and nutrient cycling. Increased soil moisture deficits will also affect soil structure through desiccation effects, modification of soil aggregates, and reductions in organic material that also influence water-holding capacity.

In addition, other supporting new evidence provides further information on drought risk. A high-resolution climate model ensemble projects an increased frequency of droughts for much of southern/eastern UK and extreme droughts for southern UK by 2041-2070<sup>8</sup> with a moderate increase in magnitude, whereas for the later 2071-2100 period there are further increases in drought frequency and magnitude, especially for projections of approximately 3°C to 5°C global warming at the end of the century<sup>9</sup> (Spinoni *et al.*, 2018). This analysis suggests drought frequency is likely to increase not only in summer but also other seasons, notably autumn. These drought assessments use a simplified method for evapotranspiration (Hargreaves-Sarmani) which may potentially over-estimate drought magnitude compared to more robust methods such as Penman-Monteith, indicating further research is required to fully investigate these biophysical feedbacks.

UKCP18 is consistent with previous projections in simulating an increased frequency of wetter winters. This has important implications regarding soil wetness risk and the duration for which soils are saturated and at field capacity. This risk, and associated soil compaction risk, are especially prevalent on agricultural land because they constrain field access and workability, and also if livestock are present to increase the soil degradation risk from poaching. As discussed in more detail in section 3.8 (Risk N6), current evidence including updates with UKCP18 suggests that the period of time with saturated soils at field capacity may actually decrease due to the longer continuation of soil moisture deficits in autumn, but there will still be a major at-risk period during winter and extending into spring when inappropriate use could cause significant damage. The role of field drainage systems in modifying this field capacity period into the future remains an important uncertainty, notably because of the lack of data on the full extent and continuing performance of the drains (due to limited maintenance). Specific issues may also be recognised in those low-lying areas where drainage is co-ordinated through Internal Drainage Boards, recognising that these arrangements have a crucial role also in maintaining soil health as well as agricultural productivity. Similarly, changes in drainage conditions in upland areas used for agriculture (including presence of artificial open drains or 'grips') is likely to have an influence on grassland quality and viable stocking rates without incurring soil degradation, but evidence for this remains limited.

---

<sup>8</sup> EuroCORDEX regional climate model ensemble with both the RCP4.5 and RCP8.5 concentrations pathways

<sup>9</sup> EuroCORDEX regional climate model with the RCP8.5 concentrations pathway

More research is also required on changes in wetting and drying spell lengths in soils due to changes in climate variability because in addition to the implications for soil structure, these are important for improved understanding of modified physical, chemical and biological processes, including leaching rates, mineralisation and microbial activity.

UKCP18 also indicates increases in rainfall intensity and when this is coincident with periods when soils are most vulnerable (e.g., bare arable soils during planting of crops in autumn or spring), there is therefore an increased risk of soil erosion. Changes in wind-driven soil erosion remain rather uncertain due to limited confidence in wind parameters in climate change projections. In practice, as with many soil-related risks, both wind- and water-driven erosion can be mostly alleviated by good management, and therefore strongly influenced by any shifts in field- and farm-scale planning that are cognisant of the risk factors.

The implications for soils that are used intensively for agriculture and forestry will strongly depend on any adaptation to the changing climate that conserves and rehabilitates soil resources. As highlighted in CCRA2, a continuation of current practices in sensitive locations is very likely to exacerbate future climate change risks due to erosion (wind and water), compaction, and loss of soil biodiversity, as a further continuation of present risks, but with potential threshold effects.

Regarding soil biodiversity, the slower turnover rates, lower nutrient requirement of fungi and their ability to degrade recalcitrant plant litter, means fungi-dominant food webs (as compared to bacteria-dominant webs) are more prevalent in low resource quality soils, which has been used to infer that they would be more resistant to climate change (De Vries *et al.*, 2012). However, this may not be the case. Sayer *et al.* (2017) used experimental site manipulations of temperature and precipitation over 17 years on a species-rich grassland near Buxton (Derbyshire) together with molecular fingerprinting. This analysis, in contrast to shorter-term studies that have reported high resistance of soil fungi to drought, showed substantial losses of fungal taxa in the summer drought treatments, primarily loss of subordinate rather than dominant taxa which were closely related to plant traits. This evidence indicates how climate change could affect soil microbial communities indirectly via changes in plant resources (leaf material, leaf dry matter content and C:N ratios), especially in nutrient-poor systems with slow-growing vegetation similar to the Buxton grassland.

CCRA2 reported on the lack of consensus regarding future changes in soil organic carbon (SOC) and this uncertainty continues (see also N5). Although evidence generally supports a conclusion that warming enhances fluxes to and from the soil, the net balance between gains from primary productivity and losses from decomposition remains more uncertain with large variations between models and single-site experiments (Bradford *et al.*, 2016). UK data was included in a global meta-analysis of multiple site-based experiments by Crowther *et al.* (2016) which suggested that net warming-induced losses would be proportional to the size of the initial soil carbon stock due to the greater potential for accelerated decomposition through temperature sensitivity. This would imply a much greater loss of SOC for higher magnitudes of climate change (including 4°C compared to 2°C scenarios), especially for areas of large carbon stocks as occur in UK peatlands. However, a more recent meta-analysis of experimental data has disputed these findings suggesting that large variations at site level tend to confound a simple interpretation based upon common dominant predictors (van Gestel *et al.*, 2018).

For peat soils, a scenario of 4°C global warming by the end of the century<sup>10</sup> would slightly increase overall blanket peat erosion for N Pennines (Li *et al.*, 2017). Predicted erosion rates were found to decrease at locations that are currently wet and cold, whilst in some warmer and drier locations they increased by > 50% indicating summer desiccation may play an increasing role in future peat erosion for vulnerable areas such as the North Pennines.

CCRA2 also evaluated evidence and uncertainties in dissolved organic carbon (DOC) fluxes from soil, with climate factors acting in combination with DOC release due to declining atmospheric sulphate deposition. Recent work has also investigated combined effects of climate and sulphate emission scenarios for nine major peatland catchments (collectively providing 57% of UK drinking water supply). This showed that changes in soil biophysical processes and reduced river discharge could cause annual DOC concentrations to increase by as much as 53% in the Severn catchment for the highest emissions scenario (UKCP09 A1FI scenario) by 2090, although the Tyne catchment had the highest mean concentrations (Xu *et al.*, 2020). Large increases (by as much as a factor of 1.6) in DOC concentration by the 2090s compared to baseline conditions are projected for autumn and winter, these being the seasons when DOC concentrations are already often high at present and when water treatment works often reach their processing capacity. This work is based upon assumed further decreases in sulphate deposition for Europe, decreasing to 36% of baseline levels by 2030 and 18% by 2090. Regarding causal processes, investigation of drought relationships with DOC has suggested that changing soil microbial processes are the dominant influence (anaerobic to aerobic conditions) and climate change could further alter these relationships in peatlands by causing a vegetation transition towards more drought-tolerant grassland species that produce DOC compositions which are harder to remove by conventional treatment processes (Tang *et al.*, 2013; Ritson *et al.*, 2017).

In addition to discolouration of water, increased DOC flux to water resources has important implications for drinking water treatment because DOC is associated with production of treatment by-products that can have severe human health ramifications (see 'cross-cutting' risks below). Hence, if raw water quality cannot be maintained through improved land management measures (e.g., blocking of artificial drainage) then investment in additional drinking water treatment will therefore likely be necessary by water companies. Water companies are already investing in improved monitoring and online sensors for DOC in treatment plants.

Although new evidence suggests an increased frequency and magnitude of wildfire in the UK due to climate change factors (see Box 3.1: Introduction), the consequences for soils are yet to be fully understood. Nevertheless, available information does suggest that increased wildfire incidence is likely to coincide with vulnerable soils, notably peat and other organic soils, for which long-term damage may occur unless fire is prevented or quickly suppressed. A key risk factor, especially for organic soils, will be the depth of the water table, and which has been lowered in many moorland or fenland locations by artificial drainage channels such that the surface peat deposits are drier in summer and hence more flammable. Projected trends towards drier summers in UKCP18 will produce a tendency to further increase soil moisture deficits and lower water tables in these vulnerable locations adding to the overall wildfire risk. This exacerbated risk may be at least partially

---

<sup>10</sup> UKCP09 probabilistic projections with the medium emissions scenario (SRES A1B)

reduced by ensuring soils are in good condition, notably by blocking of artificial drainage channels and restoration of functioning wetland ecosystems including full vegetation cover.

#### 3.5.1.3 Lock-in (N4)

The main lock-in risks are associated with unsustainable land use decisions and continuation of management practices that are a poor match with local soil types, bioclimatic conditions and topography. There is considerable evidence in the wider academic literature (e.g., evaluating agri-environment schemes or uptake of new innovations) to show that land use decisions are often strongly influenced by past decisions and therefore follow a form of path dependency. The legacy of these past decisions can therefore be the dominant factor in continuation of preferred land uses and existing practices, despite the influence of changing government policies, and new incentive schemes. For those locations where land use practices are less suited to the intrinsic soil properties, there is an increased likelihood of further degradation and that rehabilitation of finite soil resources becomes increasingly difficult as climate change increases in magnitude.

#### 3.5.1.4 Thresholds (N4)

There are important potential threshold risks for soils but identifying these in practice is often very difficult due to multiple interacting factors (climate and non-climate). For example, there are potential temperature-related thresholds for accelerated decomposition of soil organic matter which may then exceed inputs from increased primary production. However, in reality, other factors such as moisture availability and CO<sub>2</sub> concentration also have an important role. Similarly, some work has suggested that organic soils, and especially peat, have a critical temperature threshold beyond which they become less viable, as discussed in CCRA2, and these thresholds are typically used in bioclimate envelope models to infer changes in future risk levels. The CCRA3 Thresholds project (Jones *et al.*, 2020) explored such a threshold effect suggesting that a large area of UK peatland could pass such a threshold, especially in a scenario of 4°C global warming<sup>11</sup>, implying large-scale losses of peat soils and habitats.

However, such a conclusion needs to be interpreted with caution. Peat soils can be stable at higher temperatures if also accompanied by wet conditions, as occurs in the hyperoceanic climate regimes of the western UK (and also warmer areas of continental Europe), and indeed carbon sequestration can even increase in such conditions (see risk N5). Hence, the main issue is typically whether the peatland area is in good condition (ecologically and hydrologically), and has not been drained, which provides a rather greater intrinsic natural resilience and capacity to adjust to changing climate conditions. The main inference to be drawn is therefore that if peatland is in good condition, then the likelihood of most of it being resilient against climate change is rather greater in a +2°C world compared to a +4°C world, especially for westerly locations.

Another important example is thresholds related to soil erosion, notably precipitation rates in the context of climate sensitivity. The CCRA3 Thresholds project (Jones *et al.*, 2020) used a methodology for erosion potential based upon a European study using RUSLE (Panagos *et al.*, 2015) and investigated changes based upon a 30mm/day rainfall intensity threshold. Projected soil losses due

---

<sup>11</sup> UKCP18 regional projection driven with the RCP8.5 emissions scenario, driven by a global model reaching 2 °C global warming between 2025 and 2034 and 4°C global warming in the 2060s

to heavy rainfall at a UK scale increase from 4.2 Mt/yr at baseline (2001-2010) to 14 Mt/yr for 2°C global warming and 11Mt/yr for 4°C global warming. The apparently anomalous scaling of increases for 2°C and 4°C worlds is a consequence of relative change in rainfall intensity in UK regions with higher or lower arable area based upon the single climate model run utilised (therefore may be expected to vary with different model runs). It is also worth noting that these results also do not account for the likelihood of changes in land use patterns in the UK, including shifts in intensive agriculture to new areas (see Risk N6).

#### 3.5.1.5 Cross-cutting risks and inter-dependencies (N4)

Soils are structurally and compositionally inter-related with terrestrial species and habitats through functioning ecosystems and therefore fundamental for agriculture/forest productivity, carbon storage, water quality and water quantity/availability (including relating to flood and drought risk), structural stability for infrastructure, landscape character and cultural value. Hence, detrimental effects such as through unsustainable land use, pollution, or invasive species can have far-reaching consequences. Drivers and policies influencing land use intensification, such as to increase domestic food production, or increased uptake of unplanned responses through autonomous adaptation (e.g., changes in cultivation practices), can have major ramifications for soil health and in a cross-cutting context for the many ecosystem services that depend on healthy, functioning soils. Cross-sectoral analysis has shown the key role of soils, especially in considering future risks and opportunities for biodiversity, agriculture, forestry and water resources, and furthermore that to neglect to include these interactions will provide misleading information for risk assessment and adaptation responses (Harrison *et al.*, 2016).

Degradation of soils in combination with climate change is likely to lead to severe long-term issues (potentially irreversible) in affected areas. For example, with soil erosion due to poor land management, as triggered by intense rainfall most of the damaging consequences are off-site (Graves *et al.*, 2015) including for water quality (drinking water and bathing water standards), freshwater biodiversity, and GHG emissions. Soil condition and climate-related changes in moisture content also have important implications for infrastructure networks, notably from increased subsidence risk on vulnerable clay soils due to increased soil moisture deficits in summer (Pritchard *et al.*, 2015) or slope destabilisation following heavy rain events (see Chapter 4: Jaroszweski, Wood and Chapman, 2021).

Soil erosion and increased runoff is associated with elevated levels of pollutants in water courses, including coliforms, pesticides, nutrients, and toxic minerals, which have human health implications through drinking water quality and bathing water quality. In addition, increased flux of DOC into water sources has important implications for drinking water treatment because the changing character of the organic material affects its efficiency of removal and its presence can induce reactivity with disinfectants to form by-products such as carcinogenic trihalomethanes (THMs) formed when water is chlorinated to kill pathogens. Recent research using laboratory experiments and monitoring data from five full-scale Scottish drinking water treatment plants has shown significant positive correlations between THM, temperature, and DOC (Valdivia-Garcia *et al.*, 2019). This research also suggested that a 1.8 °C increase in surface water temperature in Scotland by 2050 could cause a 39% increase in THMs.

These relationships between soil degradation, ecosystem services, and human health and well-being have further implications for vulnerable people and communities, not only because they may become more exposed to impacts such as pollution or loss of livelihood, but also because their sensitivity to that exposure is greater. Such indirect effects may exacerbate inequalities, especially in rural areas.

#### 3.5.1.6 Implications of Net Zero (N4)

Soils and especially SOC are crucial to the Net Zero agenda and hence climate-related impacts on SOC will have important implications for achieving the Net Zero goal, especially for peat and other organic soils that have high carbon stocks. The Net Zero agenda is also predicated on major land use changes, including expansion of woodland and bioenergy crops, that in appropriate locations could bring substantial benefits for soil health if also consistent with both present and future climate suitability. By contrast, if such land use changes are poorly planned and implemented then the detrimental effects could be exacerbated by ongoing climate change. A cautionary example here would be the expansion of maize cropping, which is often used for anaerobic digestors and associated reduced GHG emissions, but when planted in inappropriate locations such as steep slopes can accelerate soil erosion and loss of soil nutrients. Similarly, as discussed further for Risk N5, afforestation on some organic or organo-mineral soils incurs the possibility of a loss of SOC through disturbance which could be detrimental to achieving a Net Zero emission target by 2050 (Brown, 2020; Friggens *et al.*, 2020). These examples identify the need for further spatial refinement of Net Zero pathways in terms of sustainability requirements to maintain soil quality in conjunction with the target areas for land use change, in order that incentives do not result in perverse outcomes for soil health (as exemplified by some renewable bioenergy schemes, such as those encouraging maize expansion in locations vulnerable to soil erosion and degradation).

As further discussed in Risk N5, poor implementation of climate change mitigation objectives may have negative consequences for soils. For example, a key pillar in the Net Zero plan is increased afforestation which to avoid good quality agricultural land may become planted on organo-mineral or organic soils. Unless impacts are carefully managed, forestry on such soils can increase erosion and compaction risk and actually result in loss of SOC which acts against the desired climate change mitigation outcome. As recently reported from Wales, organo-mineral soils are also often on steeper slopes and more vulnerable to erosion, whilst also being in close proximity and hydrologically connected to deep peat soils which may further extend the zone of disruption (Berdeni *et al.*, 2020).

Measures that effectively enhance soil health and resilience can therefore be synergistic by increasing the long-term capability of soils to contribute to Net Zero goals in conjunction with the multiple benefits achieved through adaptation for sustaining a broader range of ecosystem services.

#### 3.5.1.7 Inequalities (N4)

No evidence was available to show how societal inequalities may be affected in relation to risks to soils from changing climatic conditions.

## 3.5.1.8 Magnitude scores (N4)

<b>Table 3.11</b> Magnitude scores for risks to soils from changing climatic conditions, including seasonal aridity and wetness					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	Medium	High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(low confidence)	(Low confidence)
<b>Northern Ireland</b>	Medium	High	High	High	High
	(Low confidence)	(Low confidence)	(Low confidence)	(low confidence)	(Low confidence)
<b>Scotland</b>	Medium	High	High	High	High
	(medium) confidence	(Low confidence)	(Low confidence)	(low confidence)	(Low confidence)
<b>Wales</b>	Medium	High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(low confidence)	(Low confidence)

Notes: Magnitude categories based on expert judgement of existing/expected climate impact on soil biodiversity, properties, and functioning, and associated ecosystem services (except carbon storage: Risk N5). Confidence is constrained by the limited availability of national-scale data. The present risk magnitude is at least MEDIUM and may be higher but there are challenges in attributing soil degradation against multiple risk factors (climate and non-climate).

## 3.5.2 Extent to which current adaptation will manage the risk (N4)

## 3.5.2.1 Effects of current adaptation policy and commitments on current and future risks (N4)

## 3.5.2.1.1 UK wide

As identified above, although evidence remains limited due to lack of comprehensive and updated monitoring, the evidence that is available at present indicates that current trends in soil degradation are in general not being reversed. Notable exceptions can be recognised for some initiatives and locations such as through agri-environment schemes, as described below.

Despite growing recognition of the importance of soils, including for the wide range of ecosystem services they support, there is no single policy dedicated to soil and instead it is covered by a range of international and national agreements, including the legacy of EU policy. Hence, prior to the

transition to new policy arrangements occurring at present, soils were intended to be protected through cross-compliance for agricultural payments and by the UK Forestry Standard's Forests and Soils Guidelines, which identify requirements for good practice, but regulatory enforcement has been limited and primarily based upon penalties for the most severe negative outcomes rather than progress towards positive outcomes as supported by detailed monitoring (Environment Audit Committee, 2016). Agri-environment schemes have provided a more targeted approach and have delivered positive outcomes in some locations. Soil health has also been protected indirectly by measures targeting water quality as driven by the Water Framework Directive.

An important UK-level initiative that has previously provided updated information on soil properties was the Countryside Survey, which was based upon a programme of stratified sampling (by contrast with grid sampling used by the national soil inventories for England and Wales or Scotland). This initiative had added value in providing pooled data and analysis for a wide range of soil series/associations and habitat types across the UK, although the sampling strategy was primarily habitat based. However, the last published version was from 2007. A move towards a streamlined programme with a more limited collection of sample metrics has been proposed, but at present there is no new data available to facilitate comparisons between countries, including standardised sampling protocols.

Some soil types have received more attention than the general pattern, notably peat because of carbon storage and other benefits. The UK Peatland Strategy (IUCN, 2018) sits alongside the existing country level peatland plans (see below) and supports the development of additional or future plans. The strategy aims for 95% (2M ha) of peatland in good condition, under restoration, or being sustainably managed, by 2040, with an interim target of 50% by 2030.

#### 3.5.2.1.2 England

A policy aspiration as reaffirmed by the 25YEP for England is to bring all soils into sustainable condition by 2030. The Environmental Audit Committee (2016) has previously reviewed the existing rules for agricultural cross-compliance that link farm payments to good environmental condition, finding they were not sufficient to support the 2030 ambition to manage England's soil sustainably. In making recommendations for policy improvements, the same Committee report highlighted that in the past, rules were only minimally assessed and crucial elements of soil health, such as structure and biology, were not included, with the inference being that cross-compliance was overly focused on preventing further damage to soil rather than restoration and rehabilitation.

The actions set out for soil health in NAP2 are primarily focused on research and monitoring, consistent with the proposals for improved soil information in the 25YEP. Policy is also in transition towards implementation of the new Agriculture Act 2020 which includes land manager payments based on 'public money for public goods', and explicitly includes good soil management as a target outcome. The proposed Environment Land Management scheme (ELM - see Risk N1 for further details) and Soil Health Index is currently under development to be phased in during 2021-2027, with uptake of ELM a voluntary opt-in scheme linked to specific measures required for individual land managers. Work is therefore underway to develop a healthy soil indicator and a proposed soil monitoring scheme including a revised soil data baseline and the incentivisation of good management practices through ELM. Options around future soil protection to replace CAP cross-compliance regulations are also still under development but may be associated with long-term

targets. At present, however, it is too soon to confirm what these planned policies and actions will be.

Within vulnerable catchments in England, the 'Catchment Sensitive Farming' initiative has required farmers to test soils and apply fertiliser or manure accordingly to improve soil nutrient levels and meet crop needs. The rules require farmers to assess weather and soil conditions to reduce the risk of run-off and soil erosion. More recently, the Farming Rules for Water, introduced in April 2018, stipulate key requirements for all farmers to help protect water and soil resources.

#### 3.5.2.1.3 Northern Ireland

In Northern Ireland, current CAP arrangements are continuing whilst replacement policies are still being developed. The recent development of a Sustainable Agricultural Land Management Strategy recognises the existing unsustainable use of soils and identifies recommendations to address these problems. For example, less than 10% of farmland in Northern Ireland has an up-to-date soil analysis and 64% of soils are not considered to be at optimum pH. The strategy also calls for a "culture of behavioural change created by the provision of personalised information to empower farmers through measuring and managing the performance of their land", also including a central focus on soils. AFBI ran a Representative Soil Sampling Scheme from 2004/05- 2016/17 using 500 fields randomly selected from intensive cattle farms across Northern Ireland and each winter 100 fields were sampled until the work was suspended. In addition, almost 20,000 fields across over 1000 farm businesses were soil sampled in Autumn/Winter 2017/18 by AFBI through the European Exceptional Adjustment Aid (EAA) funded Soil Sampling and Analysis Scheme.

#### 3.5.2.1.4 Scotland

Current CAP arrangements are continuing in the short term in lieu of further policy development for a CAP replacement. SCCAP2 recognises that there are currently insufficient data and metrics to assess soil vulnerability to climate change and policy is now aiming to develop an improved indicator framework for soil health. For this purpose, Neilson *et al.* (2020) identified 13 potential indicators that could be used as a framework to guide regular resampling to update long-term national datasets, but this study also highlighted a critical knowledge gap regarding the dependencies and interdependencies of those indicators, especially for interactions between soil biological diversity and function. Hence, sensitivity of the individual indicators at national scale against climate change threats has not yet been established. However, maps of intrinsic risk for soil erosion and compaction have been developed based upon texture, profile and slope data for the main agricultural areas (Lilly and Baggeley, 2018), identifying the most vulnerable locations. When evaluated against changing climate exposure (rainfall intensity etc.), these maps can provide a basis for identifying where additional adaptation actions, notably through land management, are likely to be necessary, although this currently remains work in progress. For marginal agricultural lands, a framework to assess adaptation options in the context of natural capital has also recently been developed to highlight changing synergies and trade-offs (Pakeman *et al.*, 2018).

The SCCAP2 also highlights the Soil and Nutrient Network and Farm Advisory Strategy as existing initiatives that can facilitate delivery of progress on requirements for sustainable soils. The 'Farming for a Better Climate' initiative also has options for the agricultural sector that aim to link enhanced

farm productivity with improved soil protection and associated reduction of GHG emissions. There is increasing consideration of soils in the planning system (4<sup>th</sup> National Planning Framework) as part of nature-based solutions, but this is currently primarily focused on Net Zero, whilst SEPA has developed 'Delivering One Planet Prosperity' sector plans that provide guidance on soils and off-site impacts on water quality across a range of activities.

Scottish Government has also committed to increase the restoration rate of degraded peatland from the current target of 10 kha/yr to 40kha/yr after 2020, whilst its Climate Change Plan 2018-2032 update states an ambition to restore over 250kha of peatland by 2030. The same updated Climate Change Plan indicates 6kha of degraded peatland were 'restored' in both 2018-19 and 2019-20, which remains below the target level (in total 25 kha of peatland have been rehabilitated since 2012).

#### 3.5.2.1.5 Wales

Target outcomes have been developed to increase the resilience of soils in Wales, and these are reflected in the national adaptation strategy. 'Sustainable Farming and Our Land' (2019) outlines that future farm support post-EU-exit will be based around the principle of sustainability, including that farmers will receive payments for management of habitat, nutrients, and soil health, as also associated with key ecosystem services. Using UKCP18 data, the Welsh Government Soils Policy Evidence Programme (SPEP) and Climate Suitability and Capability Programme (CSCP) initiatives are providing a research framework to consider interactions between land use and soils decisions in terms of the alternative options required to maximise national resources and the further development of land use support schemes, such as Glastir.

With regard to the threat of movement from unconsolidated spoil tips, a Coal Authority safety review is presently underway that will produce a standardised approach for the future inspection and maintenance of all such sites in Wales.

Soil carbon is one of 46 National Indicators used to track success of the Well Being of Future Generations Act and progress towards the UN SDGs. The new Farmer Payment scheme being developed to replace CAP (the Sustainable Farm Scheme) includes preliminary evaluation of the climate resilience of interventions for a range of habitat types. There is also a 5-year National Peatland Action Programme now being implemented to target and coordinate restoration activities.

#### 3.5.2.2 Effects of non-Government adaptation (N4)

As reported in previous CCRA, wide variations in land management practices continue to be an issue for soil outcomes, especially for agriculture. There are some positive examples of local action and collaboration including agri-environment schemes, native woodland restoration and peatland restoration. Water utilities companies and the food and drink industry have provided soil management incentives (e.g., Mark & Spencer's Plan A; Nestle/First Milk initiative) and there are also various accreditation and quality assurance partnership schemes that include good practice for soils (e.g., LEAF; Tried & Tested; Red Tractor; Soil Association organic certification). In Scotland, the Farming with Nature programme developed by the Soil Association has promoted knowledge exchange and innovation regarding improved soil health.

Adaptation tends to be less explicitly referenced in these schemes compared to climate change mitigation but there is an opportunity for enhanced inclusion and outreach through further scheme development and to include explicit adaptation goals for local farmers. This can include guidance referenced to existing practices and exemplars of good management practices, as for example with use of no-till farming (Skaalsveen *et al.*, 2019; Cooper *et al.*, 2021) or the use of cover crops, that can enable erosion and soil carbon losses to be alleviated, with benefits for both climate change adaptation and mitigation when practices are appropriately matched to local contexts (see also section 3.7.3). Similarly, benefits of good management practice have been shown to be effective in some locations for counteracting peat erosion (Li *et al.*, 2017).

Despite these positive examples, the evidence referred to above also indicates that unsustainable land use decisions continue, based upon short-term productivity goals that neglect the wider importance of soils in adapting to climate change. Analysis of agricultural locations that have been associated with severe soil erosion in SE England indicated that most farmers would change land use or management to avert the erosion risk, in this case from winter crops to grassland, although this seems dependent on agri-environment scheme grants and their continued availability in future (Boardman *et al.*, 2017).

#### 3.5.2.3 Barriers preventing adaptation to the risk (N4)

Soils represent a hidden asset and there is a lack of full recognition of the multiple functions and benefits from soil especially when compared against agricultural productivity (Royal Society, 2020). These benefits are unlikely to be fully recognised by many private landowners, due to the time taken to realise these benefits (from improved management), or because benefits are non-market in nature and the link with incomes is indirect and not fully understood. In addition, they have not attracted the same level of NGO support as more charismatic biodiversity. Much of the negative outcomes of poor soil management are also transferred off-site (e.g., through reduced water quality downstream caused by runoff) and hence not directly apparent to the land user: Graves *et al.* (2015) estimated that up to 80% of damage costs occur off-site.

Our assessment finds that, despite recent renewed interest in the importance of soils, there remains a lack of wider understanding of the benefits of improved soil health for ecosystem resilience in a climate change context. Land use decisions (especially in agriculture), as sometimes facilitated by perverse incentives (e.g., maize-biofuels), therefore usually do not recognise the full long-term value of the soil resource, and informal land manager knowledge of indicators of good soil health has been lost. This is compounded by the complexity of soils and the large variations in space and time, including lag effects, so that cause-effect relationships that may be associated with specific management interventions are often difficult to disentangle. This means there is uncertainty around the methods, metrics, and techniques that can be used to deliver objectives for sustainable healthy soils. The problem has been further exacerbated by the lack of investment in comprehensive soil monitoring to help understand changing soil properties and the effectiveness of different management strategies.

#### 3.5.2.4 Adaptation shortfall (N4)

Although soil health is included in all of the latest UK national adaptation programmes there are not yet detailed action plans to integrate and implement these aspirations. Furthermore, throughout the

UK, planning is not yet accompanied by a comprehensive soil monitoring strategy to better understand and monitor progress on climate change adaptation in the context of other drivers, together with the effectiveness of different interventions and land management strategies, both locally and at national scale. Hence, successful implementation of current policy developments will need further refinement to include baseline and target soil property condition statements to explicitly define sustainable outcomes for soil health, as supported by comprehensive monitoring regimes at the scale of farms and their constituent land parcels, and for the uplands. At present, the only soil type to have time-bound plans for restoration and recovery are peat soils, and the emphasis has been on deep peat and primarily climate change mitigation rather than adaptation planning.

Therefore, despite increased government recognition of the need for soils to be returned to a sustainable condition, the accompanying implementation action at national scale are still considered insufficient to manage the future levels of climate change risks down to low magnitude levels. Although assessed with low confidence due to limited evidence on adaptation, knowledge of the underlying processes is adequate enough to indicate an expected increase in the severity of the risk in the absence of further realised actions.

### 3.5.2.5 Adaptation Scores (N4)

<b>Table 3.12</b> Adaptation scores for risks to soils from changing climatic conditions, including seasonal aridity and wetness			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Very Partially* (Low confidence)	Very Partially* (Low confidence)	Very Partially* (Low confidence)	Very Partially* (Low confidence)

\*Most notably for deep peat soils

### 3.5.3 Benefits of further adaptation action in the next five years (N4)

It has been recognised by several of the studies cited above that further progress in addressing this risk requires an integrated land use policy linking agricultural and forestry productivity with measures that improve soil health and resilience based upon good knowledge of the potential of different soil types and their key functions. The basis for such a response can be recognised in current developments such as ELM in England, the Land Use Strategy for Scotland, the SPEP and CSCP initiatives in Wales, and the Sustainable Land Management Strategy for Northern Ireland. However, the evidence also indicates that having a primary objective to bring soils into sustainable condition in the next decade requires that these policy developments should be also expanded to include further integration of adaptation and mitigation strategies based upon long-term planning, including for ambitious land use policies such as woodland expansion and new bioenergy crops, based upon local soil properties. This would also require improved support for land managers in terms of access to benchmarking data and advice how to improve soil health outcomes consistent with improved use of public payments to soil health tracking and outcomes. With greater technical

support to improve soil health, benefits could also be realised through improved connection of land managers back to their soil and therefore encourage more bottom-up adaptation initiatives based on different local contexts.

This assessment has highlighted the need for more comprehensive soil monitoring to help better understand spatial and temporal variability in soil properties and process in the context of both climate and non-climate drivers. For example, complete GPS soil sampling and analysis in fields at 2ha intervals has been suggested for Northern Ireland (Sustainable Agricultural Land Management Strategy) whereas in Scotland, there has been consideration of comprehensive sampling on a per field basis. In conjunction, successful adaptation will require further development of appropriate indicator metrics based upon monitoring data to measure progress and inform policy, define regulatory requirements and engage with land managers and other stakeholders. Although soil quality indicators are often proposed to assess the delivery of soil ecosystem services, more research is required to better understand the most appropriate suite of indicators and to identify baseline and target levels for use in regulation. Indicators also need to be able to be measured regularly and efficiently in the field without recourse to more detailed lab analysis, but this can be difficult because of the need for standardisation and consistency of procedures. For example, for physical properties, six soil indicators have been proposed that have high relevance for assessing soil functions and policy progress: packing density, soil water retention characteristics, aggregate stability, rate of erosion, depth of soil and soil sealing (Constanje *et al.*, 2017). For ecological indicators, high-resolution and molecular tools needed to investigate soil biodiversity and function have only recently been developed, and harmonized static datasets are just emerging, but further development is required to derive time-series data (Guerra *et al.*, 2021).

As further discussed in Risk N6, amongst the prospective suite of land management innovations that may have considerable benefits for soil protection in the next five years is development and increased uptake of precision farming technology, which can also link climate-smart adaptation actions on the ground with the Net Zero agenda. With further advances in climate services, including seasonal forecasting, as applied to agroclimate metrics (or equivalent for other land uses such as forestry), land management practices may be scheduled and targeted to avoid soil degradation at critical times, as notably occurs for soil compaction during wetter periods. Research has shown that avoidance of soil compaction is likely to be a much more effective strategy than approaches that attempt to remediate compaction damage after it has occurred, such as by subsoiling operations (Chamen *et al.*, 2015). Similarly, the advantages of no-till management systems in terms of both climate adaptation and mitigation require further trialling and policy support based upon recent evidence of multiple benefits including prevention of soil erosion, enhanced earthworm activity, and improved water infiltration, in addition to reduced costs and labour requirement (Cooper *et al.*, 2021). However, support for such strategies may require additional spatial targeting to be consistent with local variations in soil properties, hence the added value of integrating with improved soil monitoring.

A particular adaptation challenge can be identified in terms of improved risk management for spoil tips and contaminated land, and this issue requires further emphasis. A variety of engineering solutions may be applied (e.g., improved drainage of spoil heaps to avoid soil saturation) but there is also further scope for use of nature-based solutions such as phytoremediation and tree-planting to

enhance slope stability, although these will take time and they require a more proactive rather than reactive approach.

#### 3.5.3.1 Indicative costs and benefits of additional adaptation (N4)

Research is now increasingly available on the cost effectiveness of different soil protection measures, which can be applied for assessing adaptation actions, although the distinctive properties of UK soils require that analysis is not simply transferred from other countries but is instead developed through a procedure that is consistent with the UK context.

Investments in soil monitoring would seem a low-regret adaptation and a necessary precursor for subsequent improvements. As discussed in more detail for Risk N6, further investment in climate services (seasonal forecasting etc.) for agriculture and forestry, in conjunction with technological advances (e.g., precision agriculture) and improved management practices may have considerable benefits in averting and redressing many of the current negative outcomes for soils.

Economic analysis of soil protection and climate-smart agriculture generally indicates positive economic returns, although financial returns from a farmer's perspective rather than societal perspective may be limited or take longer to accrue and include non-market or off-site benefits (Kuhlman *et al.*, 2010; Watkiss *et al.*, 2019), indicating also the key role of policy support. For individual practices, measures are often highly site-specific, as reflected in large benefit-cost ratios for similar interventions in different places, and evidence on these practices as viable standalone adaptation strategies remains limited and sometimes contradictory depending on assumptions (e.g., relationship with other measures) and context. Posthumus *et al.* (2015), using an ecosystem services valuation approach, found that for soil erosion, use of tramline management, mulching, buffer strips, high-density planting and sediment traps were the most cost-effective control measures, with contour ploughing also cost-effective in some circumstances. However, the study also noted that assessments of effectiveness really need to be made at farm level or field level, because of the wide variation in biophysical and land use contexts, emphasising again the key role of outreach and guidance in stimulating proactive adaptation actions on the ground.

Previous analysis for CCRA1 and CCRA2 (Frontier Economics, 2011; SRUC, 2013) found uptake in the UK farming community and knowledge of the benefits for such measures was relatively low. For example, adaptations analysed by SRUC (2013) (with one exception, for cover crops) generated positive NPVs. These did not require long lead times and had positive ancillary benefits, but the study still identified the challenge would be to encourage farmers to adopt them. All of this suggests that while sustainable soil management approaches have potential for reducing climate impacts, their uptake requires these barriers to be addressed, and may need a combination of awareness and incentives to realise (Watkiss *et al.*, 2019) though there are obvious opportunities to provide additional incentives through revision of the current farm payment schemes. There is considerable work also happening on soil management as linked with Net Zero pathways and it would therefore obviously be beneficial to increasingly link adaptation assessments with that research.

## 3.5.3.2 Overall urgency scores (N4)

<b>Table 3.13</b> Urgency scores for risks to soils from changing climatic conditions, including seasonal aridity and wetness				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Low	Low	Low	Low

While awareness of the threat to soils has increased, current adaptation responses are not yet commensurate with the extent of the risk. Hence, although policies have been developed with ambitious aspiration targets, the actions on the ground, including ongoing monitoring and support for land managers to protect soil health are not yet in place across the UK. Given the potentially very high levels of future risk and absence of a full policy framework to drive the risk down to a low level by 2100, an urgency rating of ‘more action needed’ has been assigned for all nations.

## 3.5.4 Looking ahead (N4)

Increased investment in national-scale soil monitoring programmes including good coverage across different soil types, bioclimate zones, land uses (farmland; forestry; conservation land) and habitats would have considerable benefits for improved awareness and understanding of risks. This should also include improved monitoring of different management interventions linking both adaptation and mitigation goals without sampling bias and designed so as to ensure activities are not ‘leaking’ between sites (i.e., unintended transfer of risks elsewhere). Integrated land use scenario modelling could help ensure no double accounting occurs and interactions between sectors are captured. These improved monitoring requirements have been evaluated by a range of studies (e.g., Constanje *et al.*, 2017; Emmett *et al.*, 2017; Griffiths *et al.*, 2018; Royal Society, 2020) and could also be further extended through citizen science initiatives.

In addition to relationships with land productivity (Risk N6), it would also be extremely useful to have an improved evidence base on the climate-related implications for the wider range of multiple benefits delivered by soils (across different soil types and groups), including to maintain water quality, alleviate flooding at catchment-scale, reduce drought risk, and for priority habitats and species.

### 3.6. Risks and opportunities for natural carbon stores, carbon sequestration and GHG emissions from changing climatic conditions, including temperature change and water scarcity (Risk N5)

- Warming and other climate factors will interact with spatial variations in the intrinsic properties of different carbon stores to influence outcomes in terms of either risk (carbon emissions) or opportunity (carbon sequestration). Implications also extend to emissions from the wider range of biogenic GHGs and hence net balance of GHG emissions
- Risks and opportunities are here assessed together because of similarity in underlying processes, with the outcome varying due to the spatial and temporal interaction of climate parameters (and their magnitude of change) with other biophysical and socioeconomic factors, including land use decisions (or coastal/marine management decisions for 'blue carbon' storage).
- There is only very limited coverage of adaptation planning within carbon and GHG emissions assessments, due largely to limited information and the underlying challenges that climate change uncertainty implies for managing pathways to Net Zero.
- Risks and opportunities for natural carbon stores and net GHG balance are scored as requiring more action, with the magnitude of risk increasing from medium at present to high in future.
- The need for more action is especially urgent given the commitment to reach Net Zero GHG emissions in the coming decades.

This topic presents both risks and opportunities that occur from the effects of a changing climate on carbon stores and GHG emissions, and therefore on the UK commitment to reduce GHG emissions through climate change mitigation. In addition to CO<sub>2</sub> this assessment also includes the two other biogenic GHGs associated with the natural environment, CH<sub>4</sub> and N<sub>2</sub>O, as required to appropriately understand their combined implications in terms of the net contribution to global warming. It also covers the full range of environments: terrestrial, freshwater, coastal and marine. In this assessment we aim to show how addressing risks and maximising potential opportunities are especially associated with better alignment of climate change adaptation and mitigation strategies, which have often followed largely separate policy pathways to present.

As with CCRA2, this topic requires more action, arguably even more so now with the additional UK commitment to reach Net Zero GHG emissions in the next few decades. The magnitude of risk increases from medium at present to high in future, but currently there is only limited inclusion of climate risk assessments within carbon and GHG emissions assessments. Partly this is due to limited information, which also indicates a need for more research investigation, but also because of the underlying challenges that climate change (and other) uncertainty implies for managing and monitoring pathways to Net Zero GHG emissions across both land and sea. Our assessment is mainly based upon expert opinion, due to these constraints on evidence availability, especially for the future projections, but supported by baseline and rate of change estimates where possible.

Regarding interactions with EU-exit and Covid-19, there is limited evidence. EU-exit will have an influence through its relationship with land use patterns, especially for agriculture (e.g., trade agreements; regulatory frameworks), and their impact on soils. For Covid-19 it is too early to infer consequences but there is some evidence that monitoring initiatives have been delayed.

### 3.6.1 Current and future level of risk and opportunity (N5)

#### 3.6.1.1 Current risk and opportunity (N5)

GHG emissions in the land sector typically have the highest uncertainty range in the national GHG inventory due to the high spatial and temporal variability in emissions (or sequestration) relative to point sample data. This is because of large variations in soil type and soil processes, land use management (past and present), and climate. The interaction of these different factors often means that it is difficult to attribute the influence of climate change in isolation. Climate can have a direct effect through changes in temperature and soil moisture but also acts indirectly because it influences land management decisions. The issue is further complicated by changes in atmospheric CO<sub>2</sub> concentrations, which is modifying plant photosynthesis and primary productivity to potentially increase biomass and carbon sequestration, although this is also dependent on interaction with other climate and non-climate parameters (e.g., N availability). Conversely, emissions may occur through microbial soil processes acting on organic matter to release CO<sub>2</sub> or CH<sub>4</sub> depending on presence of aerobic or anaerobic conditions (i.e., soil wetness) and temperature. In addition, N<sub>2</sub>O emissions may occur through nitrification/denitrification processes (also linked to soil moisture levels,) either directly from soils or through aquatic pathways. Land use and land use changes can significantly modify the net GHG balance with forestry and semi-natural land uses typically having higher C sequestration potential and C stocks, whilst agriculture, depending on management practices, may deplete soil C stocks, and significantly increase CH<sub>4</sub> emissions from ruminant livestock and N<sub>2</sub>O emissions from fertiliser application.

CCRA2 evaluated existing evidence regarding changes in soil organic carbon (SOC) due to climate change and noted considerable uncertainty, especially as apparently conflicting results were also associated with different analytical protocols. The general consensus is that intensified land use patterns are usually the dominant factor explaining changes in SOC, where changes are detected, but this is not applicable to upland areas where climate change may be having a more discernible effect, possibly through associated vegetation changes rather than direct soil effects (Barraclough *et al.*, 2015). Further analysis has now become available primarily based upon topsoil analysis. In NE Scotland, no changes were detected in topsoil soil C concentrations resampled in 2017 at 37 sites when compared to samples from several decades previously, despite a changing climate during this time (Lilly *et al.*, 2019). Recent soil samples taken for the Glastir Monitoring and Evaluation Programme (GMEP), between 2012 and 2016 also indicated no change in topsoil carbon for Wales (Emmett *et al.*, 2017; Alison *et al.*, 2019). However, as soil C can change throughout the soil profile, further systematic analysis is required to understand if soil C is being redistributed through the profile and whether this co-varies with other factors (e.g., climate; land use; habitat type; N deposition). The apparent discrepancy in evidence for SOC has wider implications because it makes it difficult to confidently set a baseline for SOC, against which the further effects of climate or land use change could be evaluated (Rollet *et al.*, 2020a, 2020b).

Recent larger scale work may also help to further understand the complex interaction of processes that influence SOC levels in the context of temperature and moisture changes. Analysis of a global soil inventory of measured flux data has found that heterotrophic respiration has increased as a proportion of total soil respiration over recent decades, consistent with evidence from meta-analyses and experiments, indicating increased SOC loss (Bond-Lamberty *et al.*, 2018). In addition, a new theory for the persistence or breakdown of SOC in response to environmental drivers has linked it to functional complexity derived from the interactions between spatial and temporal variation of molecular diversity and composition (Lehmann *et al.*, 2020).

Peatland areas, which contain the largest store of carbon-rich soils, are now the focus for considerable restoration efforts because surveys suggest much of the extent is in degraded condition (most commonly due to past drainage but also due to peat extraction for horticulture and fuel etc.), meaning they act as carbon sources (with potentially quite high emissions) rather than sinks (Evans *et al.*, 2017). Evidence suggests degradation and carbon losses are further exacerbated by runoff during intense rainfall events (Li *et al.*, 2017), in addition to increased oxidation during warmer and drier conditions which cause lowering of the water table, especially on bare peat. At present, we do not have good quantitative evidence on the role of ongoing climate change in net carbon losses from peatlands because of the considerable spatial variability and limited monitoring sites, each of which has their own distinctive settings that challenge simple generalisations.

Similarly, even assuming peatlands are functional and have not degraded to become a carbon source rather than sink, the rate of carbon sequestration in functioning peatlands is quite variable (Evans *et al.*, 2017), depending on environmental conditions including climate which vary spatially and temporally. It should be highlighted here that there is also evidence of very high C sequestration rates ( $>10 \text{ t CO}_2\text{e ha}^{-1} \text{ yr}^{-1}$ ) from pristine peatlands in some locations indicating their potential as major carbon sinks (Ratcliffe *et al.*, 2018). These locations are typically associated with a mild wet (hyperoceanic) bioclimate, allowing high primary productivity, as exemplified by Dartmoor where current C sequestration rates are rather higher than measured for the rest of the Holocene, and which also suggest a high natural resilience against present-day climate change (Lunt *et al.*, 2019), although possibly not for higher magnitudes of future climate change.

In forestry management, carbon storage in trees is often estimated through association with the yield classes used in productivity assessments, and as identified in previous CCRA these yield classes will be influenced by climate change (see also Risk N6). A complicating factor in assessing ecosystem-based carbon responses to climate change is the additional fertilisation effect from enriched atmospheric  $\text{CO}_2$  concentrations, which is likely to be further compounded by changes in atmospheric deposition of pollutants (notably N and S). Analysis by Guerreri *et al.* (2020) of the climate,  $\text{CO}_2$ , and atmospheric deposition (N and S) effects on GB tree species through water use efficiency (WUE), growth and C sequestration found a variable pattern that was consistent with the north-south climate gradient, species type and stand age. For Scots pine and oak, a clear relationship of increased WUE was detected with rising temperature and increased  $\text{CO}_2$ , which may alleviate some of the effects of increased water stress and contribute to elevated productivity in northern and western locations. Results were less clear for Sitka spruce, probably due to the greater role of management for this species, and for beech, whilst results for N and S deposition and changes in C sequestration were partially confounded by structural changes during stand development.

Both peatland degradation and tree damage are associated with the effects of deer, which are increasing in numbers in many parts of the UK over recent decades, encouraged by the trend to warmer winters, with implications for carbon stocks in peatlands and woodland. This includes both native species (notably the large numbers of red deer in upland Scotland) and the recent expansion of non-native species (sika, muntjac). Further evidence on the scale of this impact is therefore required.

Climate risks to carbon stores are also manifest through wildfire risk, especially when they occur on carbon-rich organic soils and when they damage major vegetation carbon stocks, notably woodland. It has been estimated that GHG emissions of ~0.6-1.4 MtCO<sub>2</sub>e were released from a six-day wildfire in the Flow Country in 2019 (Ricardo Energy & Environment, 2019). Similarly, the large wildfire on Saddleworth Moor (near Manchester) which burned for 3 weeks in 2018 was measured to have emission rates of CO and CO<sub>2</sub> ranging between 1.07 (0.07–4.69) kg s<sup>-1</sup> and 13.7 (1.73–50.1) kg s<sup>-1</sup>, respectively, similar to what would be expected from a medium sized power station (Graham *et al.*, 2020).

Regarding coastal and marine environments, 'Blue Carbon' represents habitats and species that sequester and store carbon. In addition to the trapping of organic material by vegetation, some plants and animals capture carbon by biological metabolic processes in tissues and shells, which may eventually become marine sediments. Important stocks of blue carbon are found in saltmarsh, maerl beds, kelp forest, and seagrass beds (*Zostera*). In addition, there are substantial carbon stocks in UK offshore shelf sediments that are now being mapped in more detail, although here bottom trawling is apparently the most widespread pressure (Luisetti *et al.*, 2019, Legge *et al.*, 2020). Climate-related pressures on blue carbon resources include temperature increases and ocean acidification (reduced pH from absorption of CO<sub>2</sub>). However, considerable uncertainty exists in the dynamics of blue carbon (Thompson *et al.*, 2017) and present efforts are focussed on producing a baseline assessment of stocks. Blue carbon is not currently included in the UK GHG Inventory and concerns have been expressed that further degradation (including physical disturbance to sediments), as exacerbated by climate change, will release this carbon (or result in carbon not being sequestered) increasing atmospheric CO<sub>2</sub>. Research is currently in progress to assess this degradation risk. Using estimates of UK seagrass cover and recent carbon trading values it has been estimated that the total value of the seagrass standing C stock is between £2.6 million and £5.3 million (Green *et al.*, 2018)

In terms of burial rates associated with coastal or marine habitats, saltmarsh typically has the highest carbon sequestration potential (ca. 100-200 gC/ m<sup>2</sup>) with other habitats also providing significant opportunities notably seagrass meadows (ca. 20-70gC/ m<sup>2</sup>) and kelp forests (ca. 30 gC/m<sup>2</sup>) (e.g., Laffoley and Grimdsitch, 2009; IPCC, 2019). Going beyond generic values, in the most favourable hydrodynamic conditions, some species can locally sustain extremely high sequestration rates: for example, eelgrass rates can exceed 3300 gC/m<sup>2</sup>. However, from the perspective of the CCRA a key issue is that these rates vary strongly based upon environmental conditions, and how they vary with climate change drivers such as sea-level rise, water temperature changes, and acidification remains an important source of uncertainty. For example, analysis of seagrass habitats has reported significant variations in carbon sequestration values and cautioned against assuming values can be transferred from one site to another without incurring significant errors (Green *et al.*, 2018). Kelp forest is a 'donor habitat' rather than a major carbon store by itself, therefore exporting approximately 80% of its production with mobile kelp detritus supporting coastal food webs and

carbon sequestration over potentially a much wide area of sea (Krause-Jensen and Duarte, 2016; Smale *et al.*, 2018; Ortega *et al.*, 2019). As discussed further for Risk N14, there is evidence for changing distributions of kelp species linked to ocean warming which may impact on these inter-relationships.

For salt marsh, as reported in previous CCRAs, the ability of the marsh surface to be able to keep pace with sea level rise is strongly dependent on sediment availability. For many sections of the UK coastline, sediment availability is constrained by coastal protection schemes that aim to limit erosion. For seagrass, our interpretation of the limited evidence suggests that the overall effects of climate change remain uncertain, but most likely are negative. Seagrass meadows grow under conditions of weak to moderate wave exposure, therefore locations experiencing increasing storm intensity will be negatively affected. Seagrass also requires high light availability and therefore increased turbidity of coastal waters that may be associated with heavier precipitation events and transfer of suspended sediments in rivers would have negative consequences. Conversely, it seems likely that seagrass would benefit from continuing ocean acidification (see Risk N14) due to it providing competitive advantages over microalgae. Although kelp forests are more tolerant of wave exposure, they may also be negatively affected if storm intensity increases in exposed locations. Further increases in sea temperature would also probably be negative for kelp, although they may temporarily provide advantages by more strongly affecting other species (e.g., sea urchins) – see further discussion for Risk N14 (section 3.16.1).

Although there are existing activities to map blue carbon resources in UK waters, including by JNCC and other agencies, an important research requirement can therefore be recognised to provide ongoing mapping and monitoring of these habitats (extent and sequestration rates) in order to provide a more robust estimate of the Blue Carbon resource and its variability through time as the climate changes. This should also recognise that C sequestration (and other ecosystem services) will also be affected by the influence of climate change on ecological succession in restored habitats (Boerema *et al.*, 2016).

### 3.6.1.2 Future risk and opportunity (N5)

Our confidence is low in assessing future change due to limited evidence and sometimes conflicting findings. These conflicting results can be due to complex spatial variations in GHG flux relative to local biophysical and land use settings, including the possibility of threshold effects, and differences in analytical methods. Climate warming will interact with spatial variations in aridity (risks to soils and vegetation stocks) and/or wetness (potential opportunities in some regions) to influence outcomes in terms of risk/opportunity in conjunction with land use decisions. These decisions include changes within agriculture (e.g., no-till farming; drainage; use of animal waste; fertiliser application; crop residues), forestry (e.g., tree species; silviculture etc.) and other uses (e.g., muirburn), but also between these land uses as strongly influenced by policies for Net Zero GHG and the impact of climate change on productivity. As discussed in more detail in Risk N6, recent work assessing the implications of changing land capability in different parts of the UK through future projections indicates the potential for significant land use changes in both uplands and lowlands, especially due to modified patterns of soil wetness and drought risk. These indirect effects of climate change will interact with the direct effects of temperature and moisture mediated changes on soil

and vegetation to result in complex outcomes for carbon stocks and GHG emissions, both spatially and temporally. In addition, as described earlier, coastal and marine environments have their own drivers of change, which also imply significant uncertainties in terms of predicting future shifts in carbon and GHGs.

As was found for CCRA2, the future outcome for SOC remains rather uncertain. This is a consequence of difficulties in determining the net balance from the dynamic interaction of climate and non-climate factors on biomass C accumulation through temperature and CO<sub>2</sub> increases compared to increased soil respiration and carbon loss through soil warming. Some recent evidence tends to suggest the outcome will be increased SOC loss. For example, a deep warming experiment on mineral soil found that CO<sub>2</sub> production from all soil depths increased with 4°C warming, with annual soil respiration increasing by 34-37% (Hicks Pries *et al.*, 2017). Whole-soil warming experiments therefore suggest a larger soil respiration response than many in situ experiments (most of which only warm the surface soil) and models, but obviously more research is required to substantiate these findings, and also for organo-mineral and organic soils. At field scale, interactions with soil moisture and expected changes in atmospheric deposition (N, S) on primary productivity will also influence actual outcomes (see also section 3.21.3 for inter-connections between changes in SOC levels and other risks to the natural environment, as well as risks in other chapters). Our interpretation of the evidence is that it is also likely that there will be an increased C flux from soil through dissolved organic carbon (DOC) which may then be released as CO<sub>2</sub>, dependent on seasonal runoff patterns in different catchments around the UK (see Risk N4 for full range of cross-cutting actions that may occur from loss of SOC and associated organic matter: soil quality/productivity, nutrient loss, water quality etc.).

It also seems quite likely that there will be non-linear responses and threshold effects although the details remain elusive. Land surface model simulations driven by climate change on a pathway to 4°C global warming at the end of the century<sup>12</sup> suggest the combined climate and CO<sub>2</sub> fertilisation effect could increase vegetative carbon non-linearly in lowland grassland and woodland ecosystems with spatial variations apparently related to key soil properties (soil moisture and heat capacity) that influence the vegetation response (Boulton *et al.*, 2020).

As highlighted in CCRA2 and discussed in Risk N4 there is evidence for potential increased erosion and oxidisation of degraded peat in future. However, as discussed for current risks, the resilience of peatland is very strongly related to its condition and therefore in some locations, notably wetter hyperoceanic areas, future warming may actually increase C sequestration rates provided that the ecological and hydrological function of the peatland ecosystem has not been compromised.

Future plans to reduce emissions will also be affected by ongoing climate change, and preliminary work is now underway to investigate these interactions. In Wales, the current programme of research to update the Agricultural Land Classification (ALC) has used future land capability projections to explore the implications for the CCC Net Zero plan to plant an additional 152kha of woodland in the country by 2050. Analysis based upon medium-high (RPC6.0) and high (RC8.5) climate scenarios show that the amount of land predicted to remain suitable for sessile oak and Sitka spruce by 2080 is set to decline significantly, mainly due to soil droughtiness constraints (Bell *et al.*,

---

<sup>12</sup> The JULES land surface model driven by HadRM3 climate model with the SRES A1B scenario

2020). For the Net Zero planting ambition to be met, it is likely that planting will need to be carried out in areas with significant biophysical constraints that may result in the target yield class (i.e., carbon storage potential) not being fully met and that this may require more flexibility from the agricultural sector to release land that is no longer in the highest grades (Best and Most Versatile (BMV) land: see Risk N6 for further details).

To meet requirements for new afforestation not to occur on prime/BMV agricultural land, it is almost inevitable that some planting will need to occur on organo-mineral or organic soils. Recent work in Scotland and Wales has explored these implications, finding that carbon sequestration is highly variable, with climate an important local factor in addition to tree species, and sometimes (depending on time period of assessment) resulting in net GHG emissions rather than sequestration (Berdini *et al.*, 2020, Brown, 2020; Friggens *et al.*, 2020). In many locations, tree planting is very likely to focus on fast-growing conifers that will require enhanced drainage to become established on these soils (Sitka spruce is the most common species). Improving drainage conditions and associated disturbance involves a soil carbon loss, which may be exacerbated by the shift to warmer and possibly drier conditions in some locations. This carbon loss may be partly alleviated by good management but needs to be better accounted for in future emissions projections under the Net Zero plan. An alternative approach would be to support and enable a much greater proportion of woodland expansion through natural regeneration; native species would be more slower growing than non-native conifers but would not incur the significant carbon loss incurred through soil disturbance and drainage required for the latter to become established on wetter soils (whilst also providing important additional biodiversity benefits).

In addition to climate-related changes in CO<sub>2</sub> emissions, it is very likely that changes will also impact the flux of N<sub>2</sub>O, most notably through interaction of soil moisture and temperature with nitrification/denitrification processes that are acting on organic and inorganic fertilisers. Even in the present climate, process complexity at multiple scales means climate effects are often difficult to decipher therefore future projections remain at an early stage. The changing amounts, proportion and timing of fertiliser application will be key risk factors together with the climate parameters. It is also possible that there will be increased volatilization of NH<sub>3</sub> due to increased future evapotranspiration rates, and changes in denitrification of aquatic NO<sub>3</sub> in streams due to warming, both of which indirectly contribute to N<sub>2</sub>O emissions. These changes may have implications for the default emission factors used in GHG emission inventories and associated assessment of abatement potential.

A further risk to consider is changes in wildfire frequency and/or magnitude, which can affect carbon stocks in both vegetation and soils. Future modelling suggests a substantial future increase in wildfire risk (See Box 3.1) which may have severe implications in peatland areas or for other organic soils which are major C stores.

In addition, in a future scenario where deer numbers are unmanaged and continue to increase, aided by the continuing trend towards warmer winters, it may be inferred that carbon losses due to excessive woodland browsing (notably of young trees) and upland peatland degradation through loss of vegetation in blanket bog and associated habitats are both likely to increase. Further evidence is required to test and quantify the magnitude of this effect.

Regarding 'blue carbon' there is rather limited evidence for assessing future changes in UK stocks at present. However, global assessments and experimental work are consistent in identifying a much greater risk of loss of coastal and marine carbon sequestration at higher magnitudes of climate change as associated with both warmer temperatures and acidification risks for marine organisms (see Risk N14) and sea level rise for coastal habitats (see Risk N17).

### 3.6.1.3 Lock-in (N5)

Land use systems have considerable inertia and path dependency due to underlying sociocultural factors, meaning past preferences, choices, and decisions often have a high influence on present and future decisions. If management decisions continue to be made based upon past climate and other extraneous factors (e.g., commodity markets), then it is likely that there will be further significant GHG emissions that are exacerbated by ongoing and future climate change. Markets and other short-term economic factors, together with new international trade agreements following EU-exit, will be especially influential for agricultural land decisions, and these may act against the optimum strategy for reducing emissions. Land use policies can also inadvertently cause a significant lock-in effect, especially when they reinforce existing cultural positions amongst land managers (e.g., between forestry and agriculture). In addition, increased use of carbon offsets schemes such as in afforestation or peatland restoration without adequate consideration of how target locations will be affected by climate change over future decades also runs the risk of not producing the intended emissions reductions in practice. For degraded peatland areas, the challenges inherent in converting a net carbon source to a sink depend on the scale and extent of degradation, therefore inaction now may potentially lock-in irreversible damage at some sites and is more likely to incur additional ongoing ecosystem service losses and increase later restoration costs, if indeed restoration is possible at the later stage (Watkiss *et al.*, 2019).

### 3.6.1.4 Thresholds (N5)

There are important threshold effects, although these are complex. Most analysis has investigated temperature effects as associated with soils and vegetation C stocks and net ecosystem productivity. For example, as previously reported in CCRA2, Barraclough *et al.* (2015) identified a mean annual temperature relationship for SOC in semi-natural habitats, which was assumed to occur through vegetation feedbacks rather than direct soil-climate effects. The CCC thresholds project also analysed a putative temperature threshold for peatland stability using UKCP18 projections (14.5°C mean temperature for warmest month: Jones *et al.*, 2020). Similarly, as reported in previous CCRA2s, multivariate threshold analysis using bioclimate envelopes suggests considerable loss of blanket bog, as further demonstrated by Ferreto *et al.* (2019) for Scotland whose analysis (using UKCP09 low/med/high emissions scenarios, but climate ensemble model not specified) suggested that "more than half of the carbon currently stored in Scottish blanket bogs will be at risk of loss".

Nevertheless, as discussed above, the net balance of C emissions (and perhaps even more so N<sub>2</sub>O emissions) is related not only to temperature but also to other variables, notably soil moisture, in combination with the condition of the habitat. Upper and lower soil moisture thresholds for soil biological activity have been derived from long-term climate change experiments (e.g., Reinsch *et al.*, 2017). Furthermore, peatland ecosystems have been identified as having multiple steady states with intervening thresholds (Roebroek *et al.*, 2017), and the wide diversity of blanket bog and other

peatland habitats (e.g., species composition; soil organic content; hydrological properties etc.) mean that using general threshold limits may overlook a more diverse response. Our knowledge of the processes does suggest though that it is highly likely though that for a 4°C warming scenario compared to 2°C warming, more of the UK soil carbon stock would be lost due to associated reductions in soil moisture from increased evapotranspiration. However, the magnitude of this difference between scenarios will depend on other factors such as relationships between CO<sub>2</sub> concentration, photosynthesis, respiration, soil moisture and evapotranspiration. C stocks in soils and terrestrial vegetation will also be dependent on land use decisions.

Threshold effects for blue carbon are also highly likely but remain uncertain. Coastal habitats, notably saltmarsh, are strongly influenced by sea-level rise, and at higher magnitudes of climate change the associated sea-level rise has a higher risk of causing severe loss of saltmarsh habitats through erosion and inundation. In addition to the loss of carbon stocks which is of key relevance for Risk N5, this also has very important implications for loss of biodiversity and for other ecosystem services provided by these habitats (see Risk N17). Analysis by Horton *et al.* (2018) using Holocene sedimentary records has indicated that marshes become nine times more likely to retreat than expand when relative sea-level rise rates are  $\geq 7.1$  mm/yr. Using this analysis with future sea level rise projections suggests a major risk of tidal marsh loss for GB, with a >80% probability of a marsh retreat under RCP8.5 by 2100. For higher risk areas of southern and eastern England, an 80% probability of marsh retreat would be achieved by 2040. Conversely, under a low climate change scenario (RCP 2.6) there is a >20% probability of an expansion or relatively stable outcomes for saltmarsh over the next 200 years for Scotland and NW England; however, even under RCP2.6 there remains a >80% probability of marsh retreat beyond 2100 for southern and eastern England.

However, the critical sea-level rise threshold will also vary with the ability of the intertidal zone to migrate inland (i.e., not disrupted by coast protection schemes) and sediment availability (Ladd *et al.*, 2019). Where sediment is available, then the marsh surface can accrete at high rates which may keep pace with all but the highest future sea-level rise projections, more commonly sediment is depleted and marshes therefore are often not even able to cope with existing rates of sea-level rise.

#### 3.6.1.5 Cross-cutting risks and inter-dependencies (N5)

There are many interdependencies, notably with agricultural/forest productivity and with biodiversity (above and below ground in terrestrial systems), and in coastal/marine ecosystems for blue carbon. This shows the need for integrated decision making (policy and regulation) that covers both the land sector and similarly for marine environments, but also linking both the land and marine sectors together more consistently, with coastal environments at the interface. A central component of this integration would be to facilitate closer integration of adaptation and mitigation initiatives, which could otherwise act against each other if developed separately (see Net Zero section below).

In coastal and marine environments, there are interdependencies with management of biodiversity, fisheries, and flooding and erosion. A further significant issue arises from the interdependencies between the land and sea, which are often disrupted due to separate policy frameworks. There is therefore a requirement to ensure more joined-up decision-making across terrestrial and marine policies in the coastal zone, in particular in relation to flooding risks and loss of habitats due to coastal squeeze, which will impact net carbon storage potential.

### 3.6.1.6 Interactions with Net Zero (N5)

There is obviously a direct relationship with Net Zero, but this is especially important regarding climate change implications for the 'Net' component of the GHG balance, and the extent to which carbon sequestration will be able to offset some continuing emissions. At present, climate change projections and their biophysical interaction with carbon stocks and GHGs are not included in forward projections of the UK GHG Inventory (BEIS). This is recognised in the CCC (2020) 6<sup>th</sup> Carbon Budget report and plans are in place to include peatland emissions in future versions of the UK GHG emissions inventory. However, as reported here, there are other habitats and land uses that are highly likely to be impacted by ongoing climate change (both directly and indirectly), including crop production, grasslands, forestry, and coastal/marine environments (not currently included in the emissions inventory) in addition to changes in SOC across the full range of soil types. It is probable that these interactions will have an influence on general emission factors used to scale up habitats and land use coverages to national scale, as shown by existing spatial variations in emissions that can be associated with different bioclimatic zones, although these relationships are yet to be fully investigated.

The evidence presented here strongly indicates that if climate risks and adaptation are not factored into management decisions for the land use sector (at multiple scales, from national policy to individual land parcels), then the Net Zero target will be much more difficult to reach because gains in one area may be counteracted by losses elsewhere. It is also well established, based upon a known temperature sensitivity, that climate change risks to carbon stores and GHG emissions from the land use sector are greater at higher magnitudes of climate change despite uncertainties (due to the considerable spatial and temporal variability of emissions/sequestration rates as related to local contexts), which have resulted in wide-ranging estimates of this positive feedback relationship (Crowther *et al.*, 2016). Furthermore, from a scientific perspective, if the Net Zero target is intended to be commensurate with changes in atmospheric GHG emissions required to achieve a safe future planet for humanity, then the significant risks and opportunities that occur through coastal and marine environments need to be included in the policy process.

### 3.6.1.7 Inequalities (N5)

If the natural environment and land use sector are unable to contribute as much as planned for the Net Zero Target then this will put additional pressure on other sectors which may have ramifications for achieving a fair and equitable transition to Net Zero. It has already been recognised that plans to achieve Net Zero GHG emissions have very important implications regarding societal inequalities, with potentially an excessive burden on the most vulnerable. Therefore, depending on how these plans are further implemented and their resultant interaction with climate factors, there will be both risks and opportunities with regard to addressing those inequalities. The limited available evidence on this topic suggests it is an important topic for further research.

## 3.6.1.8 Magnitude scores (N5)

**Table 3.14** Magnitude scores for risks and opportunities for natural carbon stores, carbon sequestration and GHG emissions from changing climatic conditions, including temperature change and water scarcity

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium	High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Northern Ireland</b>	Medium	High	High	High	High
	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Scotland</b>	Medium	High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Wales</b>	Medium	High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)

Notes: Magnitude categories based on expert judgement of existing/expected climate impact on carbon stocks and GHG emissions including both from land and coastal/marine environments. This risk has been assessed as increasing from medium (present) to high (under all future projections) due to the climate sensitivity of carbon stores and GHG emissions. Confidence is medium at present (except Northern Ireland which would be low confidence) but only low for the future because of high spatial and temporal variability in the climate relationship, combined with constraints on evidence (limited sample and modelling data). It should be also noted that this assessment combines climate-related information on soil carbon stocks which seem possibly more likely to decrease (although with many uncertainties), terrestrial vegetation carbon stocks (notably in woodland) which are more likely to increase in future, and coastal-marine carbon stocks, with an uncertain net balance.

### 3.6.2 Extent to which current adaptation will manage the risk and opportunity (N5)

#### 3.6.2.1 Effects of current adaptation policy and commitments on current and future risks (N5)

##### 3.6.2.1.1 UK-wide (N5)

In England, this risk is the responsibility of Defra for the UK Government in terms of the risks from climate change to achieving climate change mitigation in the land use sector. For the DAs the responsibility lies in the Scottish Government, Welsh Government, and DAERA (Northern Ireland). The UK Climate Change Act (2008) defines the general policy framework for improving and increasing natural carbon stores, which is then further refined through responsibilities at devolved level, as also now amended by the UK Net Zero target for GHG emissions to be reached by 2050 (with separate devolved targets on 2050 for Wales and 2045 for Scotland). Northern Ireland does not currently have a Climate Act and therefore does not have its own target, although it is implicit in the UK target. This is also especially relevant as Northern Ireland is the only UK country to currently have net emissions from the land use sector, whereas the other countries are a net sink for this sector (although Wales is only marginally a sink and the relative status of countries will change when peatland emissions are fully included in the GHG inventory, as scheduled for 2022).

Although defined as a risk requiring further action in CCRA2, it is still the case across all of the UK that only limited actions to manage the risks from climate change to carbon stores or to maximise the opportunity have been developed. Most of the studies on climate change mitigation, including that feeding into the UK GHG Emissions Inventory and Net Zero GHG emissions pathways, for which the Land Use sector is crucial, do not consider ongoing climate change or interactions with adaptation policy. In addition, as noted above, coastal and marine carbon stocks are not included in the GHG Emissions Inventory (or current Net Zero planning), resulting in a general under-recognition of their importance for contributing to reduced atmospheric GHG emissions and their subsequent added importance for enhancing local resilience.

Across the UK, the woodland expansion and peatland restoration initiatives have tended to have a primary focus on the uplands (with the exception of raised bogs in lowland areas) with to-date a lesser focus on the additional carbon sequestration benefits that could be achieved in lowland agricultural soils that are increasingly vulnerable to loss of SOC through elevated temperatures. The post-CAP plans for each country that are currently in development (see Risk N6 for more details) emphasise the importance of reducing agricultural GHG emissions in line with the Net Zero commitment, whilst also noting the importance of 'climate resilience' but do not identify how emissions reduction strategies will be made more climate-resilient. Hence, the extended scope of integrating climate change adaptation and mitigation initiatives at farm level remains to be fully realised.

##### 3.6.2.1.1.1 Woodland expansion

The importance of woodland expansion in delivering carbon sequestration and Net Zero emissions for the land sector is recognised by all 4 UK nations in national forest strategies and climate change mitigation policies, although target ambitions for new planting vary by country. These policies are relevant to the level of adaptation that may be required but are not adaptation policies in

themselves as tree planting alone does not represent an adaptation to climate risk (unless it is designed to manage that risk, such as through benefits of increasing habitat extent or connectivity, see risk N1 and opportunity N3).

**Box 3.4 – Policies in each UK nation for tree planting to achieve Net Zero**

**England**

The Government's aspiration to increase woodland cover in England to 12% of total land area by 2060, from the 10% cover at present, implies planting rates of at least 5,000 hectares per year. Despite this, annual planting rates from the Forestry Commission are sporadic and show that in no recent years has the annual target been reached.

**Northern Ireland**

The current situation is particularly challenging in Northern Ireland because existing woodland cover is generally lower than the UK average and agriculture has become the largest sectoral source of emissions, actually increasing emissions by 1% from 2014 to 2018. The devolved government in Northern Ireland currently plans to plant 18 million new trees by 2030.

**Wales**

Wales also has a proportionately large agriculture sector and GHG emissions and has only made limited progress on woodland expansion to provide additional carbon sequestration. 'Woodland for Wales' (2018) commits the Welsh Government to deliver at least an additional 2000ha/yr of woodland from 2020 and further measures that would be required to deliver GHG emissions targets.

**Scotland**

Scotland has made most progress on woodland expansion but over recent years this has still been below the ambition that was set by the Land Use Strategy to deliver a sustained programme of 50,000ha of new woodland over a 5-year period from 2016-2021. These planting targets have now been reframed in the context of the 3rd Climate Change Plan, which have seen one recent year meeting the 10,000ha target (2018-19) but the increased target (12000ha) for the following year being narrowly missed. These national planting targets do not take account of where new planting is occurring (notably whether it is on carbon-rich organic or organo-mineral soils), therefore the issues raised above in terms of net carbon balance over different time periods, remain to be resolved, as do underlying barriers regarding woodland on agricultural land. It is recognised in policy commitments that the rate of afforestation needs to increase as highlighted by the considerable expansion of woodland cover identified in the CCC's Net Zero Report and Sixth Carbon Budget advice (CCC, 2020). However, these commitments are defined in terms of new woodland area, and the amount of carbon sequestration obtained will vary significantly dependent on location, including factors such as climate, soil type, previous land use, and tree species.

Although the various national strategies for the forestry sector (see Risk N6 for more details) mention 'resilience' of forest carbon stores, there is no information provided on how robust the projected increases in carbon storage in each country is in terms of the changing climate, as for example on a pathway to 2°C or 4°C global warming. As noted above, this assessment of long-term robustness may be particularly important for woodland planting on organic soils. Based upon the range of present and future climate change risks to woodland (as also described in Risks N1, N6, and N8) this remains an important omission. In addition, the influence of a changing climate on opportunities for enhanced carbon sequestration through spatially-targeted woodland creation has not yet been factored into plans.

#### 3.6.2.1.1.2 Peatland restoration

Peatland restoration activities are increasing across the UK.

##### 3.6.2.1.1.2.1 England

The 25YEP has an objective aiming to restore 'vulnerable peatlands' including an intention 'to create and deliver a new ambitious framework for peat restoration in England', and where restoration is not viable 'new sustainable management measures to make sure that the topsoil is retained for as long as possible and greenhouse gas emissions are reduced'. Defra is currently developing an England Peat Strategy, as committed to in the 25YEP, the release of which is expected in spring 2021. In addition, the Nature for Climate Fund aims to restore 35,000 hectares of England's peatland by 2025. The Lowland Agricultural Peat Task Force will commence work in 2021 with the aim of developing new sustainable management measures for these locations.

##### 3.6.2.1.1.2.2 Northern Ireland

Peatland restoration is being implemented at a range of sites but as yet there is no national strategy or target for delivery.

##### 3.6.2.1.1.2.3 Scotland

The national Peatland Plan, as implemented through the Peatland Action initiative, aims to increase restoration from the current target of 10kha/yr to 40kha/yr after 2020 (and to restore 250kha by 2030), with current restoration activities covering an area exceeding 20kha. In addition, the plan aims to improve the condition and resilience of the wider peatland resource. SCCAP2 has indicators to monitor progress on peatland restoration area and also soil carbon stocks across all soil types. Current data indicates 6kha of degraded peatland were used for restoration activities in both 2018-19 and 2019-20, which remains below target levels (in total 25kha rehabilitated since 2012).

However, as with woodland expansion, there is a lack of evidence that peatland restoration plans are including a robust representation of the long-term ecological and hydrological functioning and resilience of individual restoration sites in the context of a changing climate, including 2°C and 4°C pathways. For example, analysis in Scotland has suggested that much of the restoration to-date has occurred in locations where incentives have attracted interested landowners (especially NGOs) rather than to be targeted at sites where carbon sequestration benefits would be maximised both in the present and future climate (Brown, 2020).

#### 3.6.2.1.1.2.4 Wales

In Wales, the Peatland Policy aims to ensure all areas of peat supporting semi-natural habitat are brought under sustainable management including plans to restore a minimum of 25% (ca. 5,000 ha) of the most modified areas of peatland back to functional peatland ecosystems. This is now being coordinated and monitored through the recently published Peatland Action Programme. The All-Wales Peatland project initiated through the Rural Development Programme also aims to support peatland restoration.

Natural Resources Wales has undertaken a carbon status assessment of the Welsh Government Woodland Estate. This is intended to inform management decisions for restoring and expanding key peatland sites.

#### 3.6.2.1.1.3 Marine and coastal carbon stores

Since CCRA2 there is increased awareness of the importance of marine and coastal C stocks as 'Blue Carbon', including initiatives for restoration (e.g., Natural England £2.5M Seagrass restoration fund) that are being trialled at various sites (e.g., seagrass restoration at Dale Bay, Wales). Improved assessment of carbon storage is also included within Marine Protected Areas initiatives for individual countries. For example, assessment of blue carbon resources in Scotland's inshore MPA network has shown the synergies that exist between reducing climate change risks and net-emissions reductions, and the role of the MPA network in achieving these synergies.

However, specific targeted actions for adaptation relating to marine and coastal C stocks (blue carbon) are in the early stages and changes in these stocks are not currently included in the UK GHG Emissions Inventory (although this is technically possible in terms of UNFCCC Wetlands Guidance). For this reason, potential opportunities for carbon sequestration as one of the multiple benefits that may be obtained from managed coastal realignment are usually not formally included in options appraisals.

In some cases, sectoral policies are in place which may protect C stocks, such as for soils or priority habitats, but they lack a cross-sectoral strategy, meaning they may sometimes be in competition (e.g., forestry expansion and peatland restoration) and not necessarily targeted at the most appropriate locations.

Our assessment is that the lack of evidence on the changing outcomes from interactions between adaptation and mitigation policy means there is considerable uncertainty for this risk/opportunity topic, especially for future risks, which has been a particular problem for climate change mitigation policy (both for the land sector and coastal/marine) as it has sought to show a viable pathway to Net Zero emissions. Hence, there is a strong need for more systematic monitoring and research in the context of the variety of different initiatives to enhance carbon stocks and reduce GHG emissions (i.e., 'what works, where, and when') in order to inform spatially targeted policy and stress testing of mitigation policies against climate change projections and adaptation plans.

### 3.6.2.2 Effects of non-Government adaptation (N5)

Again, there is very limited evidence of adaptation actions that have been integrated with mitigation strategies to protect and enhance current and future carbon stocks, or to maximise net gains for carbon sequestration. However, some land management initiatives, such as those delivering wetland restoration, enhancement of soil organic matter, or native woodland habitat regeneration are very likely to deliver both adaptation and mitigation outcomes through their multiple benefits, although more evidence of this is required.

With regard to soils, investigation of the prospects of achieving the '4 per 1000' soil carbon sequestration initiative (Sousanna *et al.*, 2019) has identified a series of practical barriers based upon resource availability, economic viability and trade-offs with agricultural productivity (Poulton *et al.*, 2018). These barriers are likely to be further accentuated by the concurrent requirements for farmers to adapt to the changing climate, unless improved advice and support is provided. For lowland peats, intensive farming is often highly productive because of the high intrinsic soil quality (unless severely degraded) and although shifts to lower intensity land uses that are more consistent with continued carbon storage are potentially technically feasible, the opportunity cost of loss of market income can be substantial. Therefore, in the context of the current post-CAP transition and reformulation of agricultural support schemes, further policy incentives will be required to address this trade off and recognise the 'public good' of active carbon sequestration.

The Scottish Blue Carbon Forum partnership has become active in promoting and developing a research agenda for improved understanding of blue carbon issues, and uptake of the research into policy, although as yet this has not been included within the adaptation policy agenda.

In Pembrokeshire, Wales, a collaboration between Sky Ocean Rescue, WWF and Swansea University is taking place to restore 20,000m<sup>2</sup> of seagrass, providing decarbonisation benefits, and adaptation benefits to marine wildlife.

### 3.6.2.3 Barriers preventing adaptation (N5)

The societal benefits from carbon storage and avoided emissions of greenhouse gases have been undervalued and the benefits to the land manager are not usually directly apparent, even where associated with soil quality for highly productive land. They have therefore in practice been treated as an externality that runs tangential to primary goals to improve land productivity for food and fibre, or in the uplands to enhance stocks of particular species (notably red grouse) for hunting and shooting.

In some cases, the scientific literature has been critical of exaggerated claims for carbon sequestration from woodland expansion or through the '4 per 1000 initiative' for soils; as these claims have been extrapolated from limited evidence, they do not provide the full picture in terms of the need for a range of robust and varied strategies to successfully match with diverse local contexts. For example, the prominent global assessment by Bastin *et al.* (2019) has been criticised for excluding soil carbon stocks when assessing afforestation potential, and analysis by Poulton *et al.* (2018), referred to above, identifies significant practical barriers to meeting the '4 per 1000' soils target. In addition, work in Scotland and Wales, also referred to above, indicates that at least some

of the woodland planting will be on ‘sub-optimal’ land and therefore may not reach optimal yield classes and the carbon sequestration potential that has been assumed.

Some aspects of existing land management practices can also be a barrier to objectives for enhanced carbon stores and reduced GHG emissions. In addition to challenges for the agricultural sector in reconciling production goals with a reduced GHG footprint, in upland areas the use of land primarily for red grouse shooting and deer stalking needs to reconcile practices (e.g., drainage, burning) that enhance grouse/deer numbers with sustainable habitat and soil conditions that maintain carbon stocks as well as biodiversity and wider ecosystem services to society.

An additional challenge is that restoration of fully functioning ecosystems that maximise carbon sequestration is difficult and requires a long-term strategy. For some habitats, such as seagrass (van Katwijk *et al.*, 2016), evidence also suggests that restoration needs to occur on a large scale to be successful.

Finally, there is a strong need for an integrated approach to GHGs (and other negative emissions) in land management that extends beyond a focus only on CO<sub>2</sub> emissions, therefore including CH<sub>4</sub> and N<sub>2</sub>O in risk assessment to avoid pollution swapping.

#### 3.6.2.4 Adaptation shortfall (N5)

Across the different UK administrations, the evidence available to us suggests there is only very limited coverage of adaptation planning within carbon and GHG emissions assessments and plans. For the future, we assess there to be a significant shortfall in adaptation for England, Wales, Scotland, and Northern Ireland, well below that required to manage risks down to low magnitude level, given the lack of attention being paid to these climate risks in the context of achieving carbon storage and sequestrations goals. Confidence here is low because of limitations of existing evidence for both the land and marine sectors but knowledge of the underlying processes is adequate for us to highlight the reasons for concern. In addition, current plans to reach Net Zero by 2050 (2045 for Scotland) cannot be considered robust in relation to this risk as they do not include stress-testing against a range of climate change projections, especially higher-end scenarios which remain possible either due to socioeconomic factors (delayed global decarbonisation) or exacerbated climate feedbacks.

#### 3.6.2.5 Adaptation Scores (N5)

**Table 3.15** Adaptation Scores for risks and opportunities for natural carbon stores, carbon sequestration and GHG emissions from changing climatic conditions, including temperature change and water scarcity

Are the risks and opportunities going to be managed in the future?			
England	Northern Ireland	Scotland	Wales
No (Low confidence)	No (Low confidence)	No (Low confidence)	No (Low confidence)

### 3.6.3 Benefits of further adaptation action in the next five years (N5)

Achieving Net Zero across the UK assumes major changes in carbon stocks achieved through afforestation and peatland restoration, although the locations for these are not yet specified in policy. As identified above, climate change brings both risks and opportunities for both peatland and woodland, together with other C stocks, and these have a strong spatial dimension. This indicates that a more spatially-targeted strategy for land use change initiatives is highly likely to deliver greater benefits for net GHG balance than an untargeted approach. For example, peatland restoration in areas that will continue to have a cooler, wetter climate and avoiding afforestation with exotic conifers on wetter organic soils (which will require artificial drainage) or afforestation on drier drought-prone soils would help to maximise carbon gains in the required timeframe.

Similarly, improved targeting of appropriate land management schemes based upon their applicability across the wider range of soil types and climate parameters would seem to provide considerable advantages for soil carbon gains. For example, recent research has identified that no-till management systems can provide significant benefits for enhanced soil carbon storage, in addition to other benefits (soil quality, water quality, biodiversity etc.), although with notable spatial variability (partly related to climate factors) compared to conventional tillage (Cooper *et al.*, 2021).

To realise these opportunities and minimise risks will also require improved data on changes in carbon stocks, especially in soils, as achieved through enhanced monitoring across diverse land use, management and climate combinations; carbon certification schemes may be valuable in providing some of these data as associated with the Woodland Carbon Code and Peatland Code. There are also likely to be substantial gains both for adaptation and mitigation through improved agricultural N-use efficiency and avoided air (N<sub>2</sub>O, NH<sub>3</sub>) and water pollution (NO<sub>3</sub>) as recently summarised through indicative analysis for the CCC (2020) Land Use Report.

In addition to enhanced adoption of agroecological approaches (e.g., cover crops; no till; regenerative grazing systems) and improved scheduling of land management activities to avoid disruption to soil carbon stocks, proactive adaptation measures can also take advantage of technological innovations, such as occurring through 'precision farming', to enable better targeting of management activities (Risk N6). Further development of integrated adaptation/mitigation initiatives will also require improved support and outreach for land managers in order to further encourage uptake and knowledge exchange on good management practice. Initiatives such as the Farm Advisory Services for each country and 'Farming for a Better Climate' in Scotland provide pathways to take forward this joint adaptation and mitigation approach.

Benefits would also be achieved by improved assessment and integration of Blue Carbon into initiatives for coasts and marine environments, notably for managed coastal realignment and restoration of intertidal areas and seagrass beds. Increased use of natural adaptation solutions would have co-benefits beyond carbon storage, including alleviation of coastal flooding/erosion risks (see Risk N17) and as a nursery habitat for marine biodiversity (see N14 and N15). Analysis by Luisetti *et al.* (2019), comparing different managements scenarios over the next few decades, has indicated that conservation of coastal and marine habitats is the best option in terms of net carbon storage gains, but that restoration can also be cost-effective although in this case with more complex trade-offs against other policy objectives.

### 3.6.3.1 Indicative costs and benefits additional adaptation (N5)

Evans *et al.* (2017) estimate current annual emissions for English peatlands as around 11mt CO<sub>2</sub>e (other studies given different estimates but around the same order of magnitude). If published non-traded central carbon values and the standard 3.5% discount rate are applied to these, the implied Present Value damage costs up to 2040 are around £13.7bn without further degradation.

Restoration is a low regret action for degraded peatlands (CCC, 2013), with early action having short-term benefits as well as longer-term resilience to climate change. Moreover, early action is desirable given that restoration to a near-natural, fully-functional state can take decades or longer and that restoration costs increase with the degree of degradation faced. There has been some analysis on the costs and benefits of restoring peatlands and enhancing carbon storage (Moxey and Moran, 2014; Bright, 2019, Watkiss *et al.*, 2019), which indicate that restoration is generally worthwhile in most (but not all) cases, for both upland and even lowland peatlands, especially if a broader range of ecosystem services are included (Glenk and Martin-Ortega, 2018). However, these assessments are largely yet to include climate risks and the need for adaptation in achieving these objectives, and also the timing of costs and benefits. In particular, capital investment costs are incurred upfront whilst benefits accumulate more slowly over time (as do any opportunity costs). This makes the choice regarding both the time period over which comparisons are made, and the discount rate by which future costs and benefits are translated to an equivalent Present Value, important. Information does indicate that reliance on voluntary enrolment (rather than regulatory obligations) is likely to limit restoration, because of necessary capital investments but also interactions with (especially) agricultural policy support and market returns (the latter gives rise to high opportunity costs for productive lowland sites) and suggests further action will need incentives.

Economic assessment of carbon storage and GHG issues for other soils, and for the marine sector (wetlands and blue carbon) as a whole remains less available. Forestry is discussed in Risk N6.

### 3.6.3.2 Overall urgency scores (N5)

**Table 3.16** Urgency scores for risks and opportunities for natural carbon stores, carbon sequestration and GHG emissions from changing climatic conditions, including temperature change and water scarcity.

Country	England	Northern Ireland	Scotland	Wales
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Low	Low	Low	Low

We assess that more action is required to integrate adaptation and mitigation policy agendas, given the very large scale of the risk and the absence of integration of adaptation considerations in mitigation strategies aimed at increasing natural carbon storage and sequestration. This includes:

- Stress-testing of proposed measures in Net Zero pathways against the wider range of climate change risks, including the full range of climate projections (2°C world; 4°C world etc.)
- More targeted actions to restore degraded carbon stores, particularly peatlands.
- More strategic approach to land use planning, integrating agriculture and forestry, based upon linking net GHG gains with other multiple benefits.
- More strategic approach in planning and decision-making to integrate the use of land, coast and marine effectively, recognising their interdependencies through development of appropriate policy frameworks.
- More research needed to account for climate change risks to carbon stores in UK GHG Inventory projections (including appraisal of emission factors)
- Better integration of Blue Carbon in adaptation/mitigation planning and reporting
- More investigation of integrated adaptation/mitigation benefits from N-use efficiency in agriculture
- Systematic programme of soil carbon monitoring (including lower soil horizons rather than just topsoil) for diverse land uses, bioclimatic zones, management interventions etc.

### 3.6.4 Looking ahead (N5)

For CCRA4, an integrated programme of research to assess pathways to Net Zero GHGs that are also stress-tested for their robustness against climate change projections (notably UKCP18) would be beneficial. This could collate and evaluate empirical and model data on changes in carbon stocks and GHG fluxes to assess net GHG balance in different contexts. These developments may also be linked with GHG ‘smart inventory’ improvements and an improved evidence of outcomes (and resilience of those outcomes) for a wide range of management options (‘what works, where, and when’) which can be used for spatial targeting of the national adaptation programmes for each UK nation.

## 3.7. Risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind) (N6)

- Forestry and agriculture have a close relationship with climate due to its influence on the viability of different crops or livestock, and on land management activities.
- There is good evidence that weather and climate variations affect both utilised land area (forestry and agriculture) and yields, and, in therefore overall productivity. This includes both risks and opportunities through the multifaceted effects of heat and cold, wetness and drought.

- While opportunities from climate change are available (notably due to longer growing seasons), risk magnitude is assessed to increase from medium at present to high in future. This is due to both increased climate exposure (heat stress, drought risk, wetness-related risks) and inherent socioeconomic factors in the land use sector that increase sensitivity and vulnerability, especially for agriculture.
- The assessment identifies limited evidence on adaptation actions and a significant adaptation gap in addressing this risk, especially for agriculture, which also highlights the importance also of continuing research on adaptation strategies.
- The increased level of evidence since CCRA2 indicates an urgency rating of 'More Action Required' because of the significant lead time to develop and implement actions in the land use sector.

This topic covers implications of climate change for the productive capacity of agriculture and forestry, notably for crops, livestock, milk, timber and other fibres. Risks and opportunities for productivity are a key topic because they affect not only land managers and rural communities but also the whole population through changes in domestic food supply and other commodities. In addition, a healthy natural environment requires that production goals are achieved through sustainable practices that do not adversely degrade biodiversity, water, soils, and other ecosystem services, with climate change having important implications for achieving that sustainable balance.

At national scale, productivity is an outcome of the utilised land area for different produce and their unit value (yield). We have good evidence that weather and climate variations affect both the utilised land area and yields, and hence productivity, and this includes both risks and opportunities through the multiple varying effects of heat and cold, wetness and drought. As with other aspects of the natural environment, the relationship between climate and agriculture or forestry is mediated through key bioclimate parameters such as the growing season and associated plant phenology effects, soil moisture variations, frost frequency, and wind exposure. Variations in solar radiation (i.e., sunshine hours) are also a key factor, especially at crucial times of year such as spring and early summer for cereals, and this can show considerable inter-annual variations. These parameters determine the viability and hence overall productivity of different land uses, and, in addition to longer-term trends, vary from year to year, sometimes accompanied by extreme events such as drought, heatwave, or flooding. Humidity can also be an influencing risk factor, as notably in terms of thermal humidity risk for livestock and the incidence of specific pathogens (see Risk N7 and Risk N8).

Distinguishing longer-term trends in productivity due to climate change is more difficult, due to the complexity of interactions, both in biophysical terms, and with socioeconomic factors. During the latter part of the 20<sup>th</sup> century, major gains in productivity were achieved through advances in technology and associated use of genetics in breeding and selection, especially for crops, although this upward trend has been less evident in the 21<sup>st</sup> century to-date. In addition, incremental changes such as the general increase in temperature have been interrupted by sporadic extreme events or combination of events, which have disrupted some types of production, typically those with more intensive requirements (notably arable or horticulture, but sometimes also types of livestock farming).

Nevertheless, there is clear evidence that climate change is modifying the productive capacity and will continue to do so in future, with a close relationship to the magnitude of climate change. In land use planning, the varying capability and flexibility of land areas for different potential uses is a key strategic tool to help maximise and protect land resources, as defined using the interaction of climate with other biophysical criteria, notably soils and topography. This provides the basis for national land capability classification systems: Agricultural Land Classification (ALC) in England, Wales and Northern Ireland; Land Capability for Agriculture (LCA) in Scotland. Grading of land therefore defines the most productive and versatile land: Best and Most Versatile Land (BMV) in ALC and Prime Agricultural Land in LCA. As described below, analysis of both classification systems shows important geographic variations in land resources in recent decades and especially in the future when drought risk is inferred to become a much more significant factor, and hence the availability of irrigation water is very likely to become an increasing concern. As noted above, in addition to these changing biophysical factors which define the potential productive land use, actual production outcomes will be strongly influenced by changing socioeconomic factors such as market prices, local traditions or land manager preferences, and policy drivers (e.g., incentives; regulations etc.).

As with previous CCRA2s, this assessment recognises that in addition to finite land resources, productivity is also dependent on interactions with healthy soils, water, and biodiversity, hence we aim to evaluate risks/opportunities in the context of sustainable production systems, including implications for both the quantity and quality of produce.

Although some opportunities are available, risk is evaluated to increase from medium at present to high in future, and with a significant adaptation gap in addressing this risk, especially for agriculture. Since CCRA2, more evidence has become available on this topic. This new evidence in combination with that used for the previous assessment suggest that the urgency rating should now be 'More Action Required' because of the significant lead time to develop and implement actions in the land use sector. However, important knowledge gaps also remain which highlight the importance also of continuing research on adaptation strategies.

EU-exit will also have an important influence on this risk topic although, as both trade agreements and post-EU-exit land use policy are currently in flux, it is not possible to identify with any certainty how this additional factor will modify both risks and opportunities. Covid-19 is an additional factor that may also modify expected outcomes but at present there is very little evidence on how much an influence this will be for overall productivity.

### 3.7.1 Current and future level of risk and opportunity (N6)

This section is structured through firstly providing an assessment of key climate (and non-climate) factors in terms of general exposure and sensitivity, including also how this is related to land quality through capability and suitability criteria. Then a more specific assessment of the evidence for specific sectors is provided in terms of consequences for production.

### 3.7.1.1 Current risk and opportunity (N6)

#### 3.7.1.1.1 Climate exposure and sensitivity

The influence of climate change can be considered both in terms of incremental adjustments to long-term trends, and the risks from changing extreme events. In terms of the primary bioclimate factors that are used in land classification, the average length of the annual growing season has increased (ca. 15-35 days for grass since 1961-90) which may be identified as an opportunity. Also, the intensity and speed of the growing season has increased: in the most recent decade, annual average growing degree days were 15% higher than the 1961–1990 average and 5% higher than the 1981-2010 average with a clear upward trend over the last 60 years (Kendon *et al.*, 2020). This latter trend may be both an opportunity and risk (depending on the crop and its thermal requirements) through its modification of plant phenology. Bioclimate data for changes in the seasonal moisture balance show a more complex pattern due to the greater influence of shorter-term variability (interannual and interdecadal) but in terms of longer-term trends some important eastern agricultural areas have experienced increased soil moisture deficits, whereas some western districts have been affected by wetter winter conditions (Keay *et al.*, 2014; Brown, 2017), with variable effects in autumn and spring. As discussed below, the influence of extreme events (e.g., drought; flooding and waterlogging; heat stress; cold spells) is evident in specific years and in locations more exposed and sensitive to these extremes but detecting changes in these extremes remains difficult, especially for precipitation-related events due to large interannual variability.

Yields and national productivity (as summarised in annual statistics provided by Defra, the Forestry Commission, and the DAs) are difficult to attribute against climate-related trends due to other agronomic and forestry factors. Nevertheless, climate sensitivity is particularly shown by specific years when productivity was strongly affected. For UK average wheat yields, the extremely poor year of 2012 (6.8t/ha) has been highlighted in previous CCRA, but in more recent years although the 5-year average 2016-2020 was 8.4t/ha, both 2018 (7.8t/ha) which featured a hot dry summer and 2020 (7t/ha) which had a very wet winter and dry spring, have been marked by significant yield losses. By contrast, 2015 and 2019 had above average UK wheat yields, showing the considerable inter-annual volatility. UK barley yields (combining winter and spring varieties) also decreased by 9.1% from 2019 to 2020 but as there was a significant increase in spring barley production area following the wet winter in 2020, meaning the combined result was a 38% increase in spring barley production. In comparison, the total UK wheat production for 2020 decreased by 40% compared with 2019. For other crops, after the hot dry summer of 2018, carrot yields were reported down 25-30% and onion yields down 40% on a normal year whilst potato yields were down on average 20% in England and Wales (Climate Coalition, 2019). These figures also show that the magnitude of risk/opportunity also varies dependent on species (and also variety/cultivar) and their individual sensitivities to climate parameters. In addition, yield impacts also vary with site location and management; for example, on heavier soils, higher water retention capability typically means that yields are less adversely affected by drought but conversely these locations are usually more negatively affected when seasonal conditions are wetter than average.

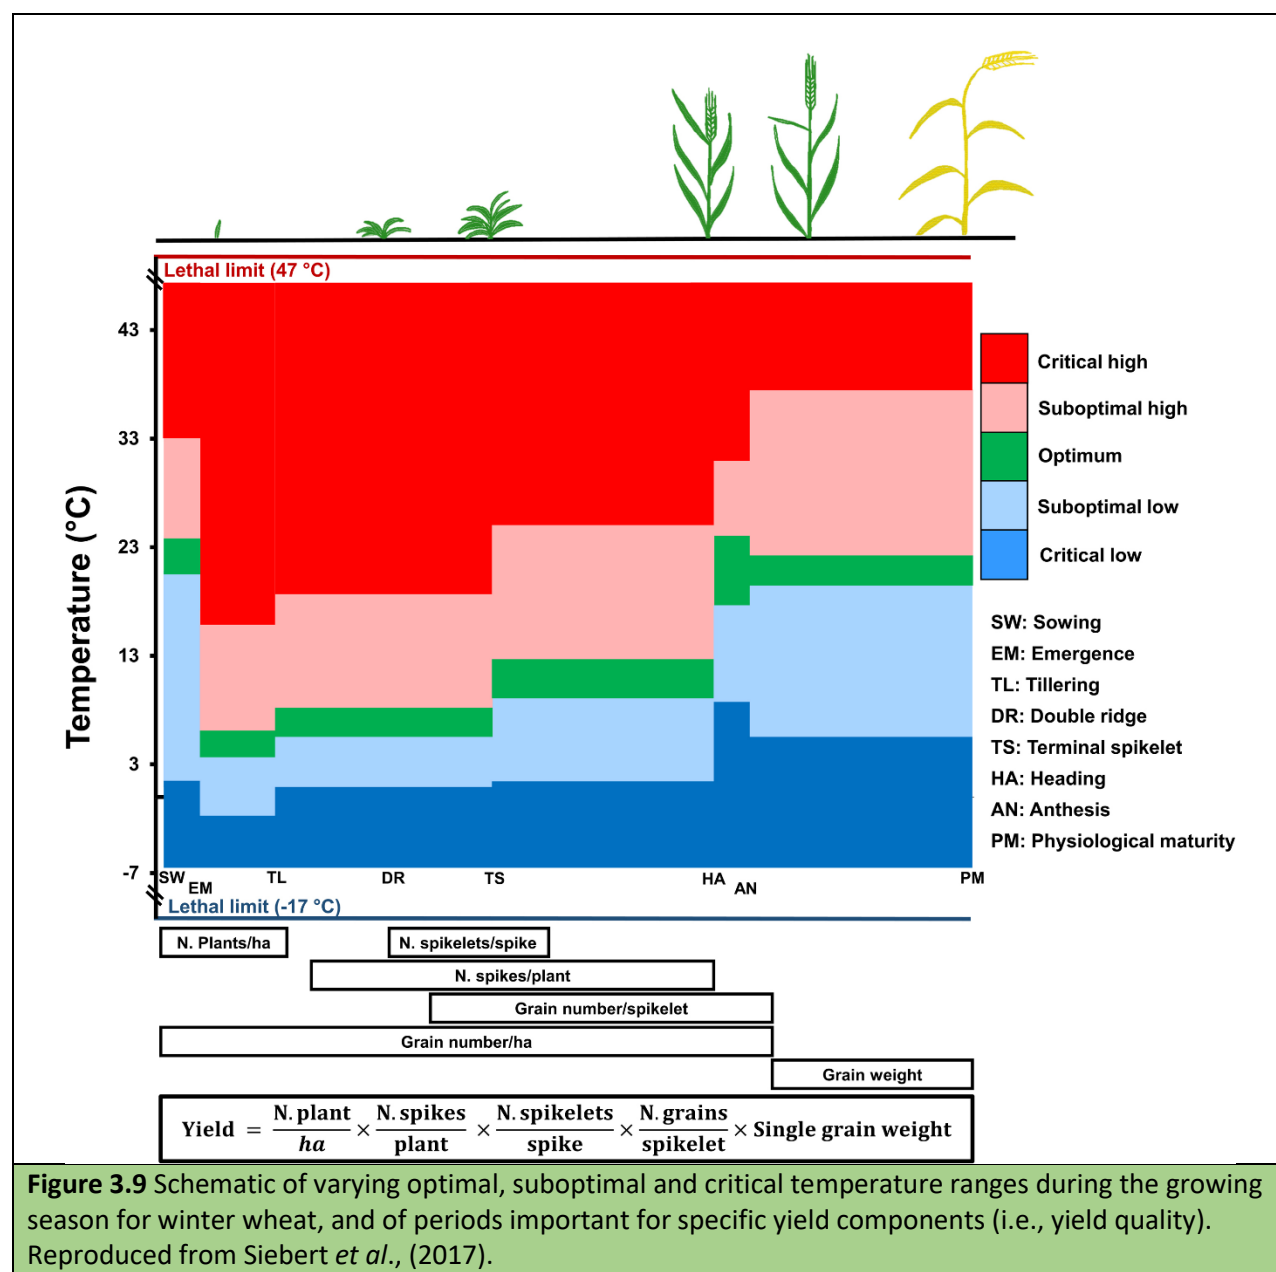

The impact of anomalous weather conditions on agricultural production is also being shown more clearly across Europe. This evidence has relevance to the UK because in some cases the impact of

such extreme conditions is indicative of the changing risks for UK production too, even if not manifest yet. In France in 2016 (most notably in NE France), an unforeseen and unprecedented severe wheat yield loss occurred which has been shown to be the consequence of a new type of compound extreme event combining abnormally warm temperatures in late autumn and abnormally wet conditions in the following spring, with these types of events expected to become more frequent in future (Ben-Ari *et al.*, 2018).

New evidence provides firmer support for inferences on climate change sensitivity made in CCRA2, although challenges in interpretation still remain. Regarding temperature changes, as noted above there is clear evidence for changes in growing seasons and phenology for many crops. Observed temperature changes also show a decline in spring frost frequency and this has also been associated with an impact on some crops, such as for blackcurrant yields (CCC, 2018b). However, relationships are typically more complex than may be initially assumed: seasonal advancement of plant phenology has been shown in wheat to vary with the selection of different cultivars (Rezaei *et al.*, 2018), and there are important interactions with vernalisation in some plants (see below). Furthermore, temperature may not be the dominant influence for some crops: for example, field data have shown a greater sensitivity of spring barley to precipitation rather than temperature variations during the growing season in Scotland (Cammarano *et al.*, 2019). In addition, recent decades have seen a trend towards increased solar radiation for some areas of the UK during the growing season (see Chapter 1: Slingo, 2021); it is likely that this has also contributed towards productivity changes, although evidence is limited and interannual variability has also continued to be large.

Regarding water-related risks, the wide variety of UK geographies in which agriculture occurs means that climate-related risks can include both the effects of too little water (water scarcity; additional effects of drought; and restrictions on the right to abstract water) and the effects of too much water (excess soil moisture restricting aeration and plant growth; waterlogging and flood inundation affecting access to land and its workability and trafficability). As noted above, these risks are currently changing due to shifting patterns of rainfall distribution and resultant seasonal soil moisture variability. We can then infer that the inherent climate sensitivity means that water-related risks will be further modified under ongoing climate change with important implications for land use decisions and national productivity. For outdoor irrigation, field crops currently account for 42% of direct abstraction for agriculture whilst a further 40% is used for drinking water for livestock for which private water supplies are particularly important (79% of requirements for dairy cattle and >90% for pigs, sheep and poultry) (Hess *et al.*, 2020).

When comparing the relative influence of different climatic factors, indicators can provide a simplifying mechanism to compare different influences. For example, analysis comparing different extreme weather indices for 1980-2010 for wheat yield at global scale has included results for the UK (Zampieri *et al.*, 2017). This work found water stress is currently a more dominant factor than heat stress for the main wheat producing areas of southern and eastern England, but also that excess wetness is currently a greater risk factor for much of the UK especially in the north. However, these analytics have been criticised by others as over-simplistic (e.g., Siebert *et al.*, 2017) due to the varying interacting effects of climate parameters across the growing season which even for temperature are complex (Figure 3.9) and may also vary between cultivars.

Climate sensitivity therefore seems a key issue both for different cultivars and different crops. As cultivars have been developed and matched to specific conditions, changes in agroclimatic parameters and frequency of extreme events requires a shift in cultivar choice and new crop breeding programs (Mäkinen *et al.*, 2018). Nevertheless, evidence from Europe suggests current utilisation of available cultivars for wheat remains limited, which constrains resilience and adaptability (Kahiluoto *et al.*, 2019).

### 3.7.1.1.2 Arable and horticulture crops

As identified in CCRA2, and further shown by the updated observed climate data provided by UKCP18, frost days have reduced in frequency across the UK, and this provides benefits for both arable agriculture and horticulture, through reduced incidence of frost damage for vulnerable crops. However, this general warming pattern also has a negative aspect because many tree species and

other crops need an effective vernalisation period of cold weather to produce a good crop every year. Minimum temperature thresholds vary according to species and cultivar, typically with a period of low temperatures needed to induce dormancy in early winter and also a further period of low temperature for dormancy release. Recent work on vernalisation in oil seed rape has suggested that changes in early winter temperatures may actually be the dominant influence (Brown *et al.*, 2019) but further work is required to ascertain the full implications of changes in minimum temperatures.

This reduced vernalisation effect is probably the main impact of climate change for UK soft fruit production at present, most of which is now under plastic (or other) protection, although a comprehensive large-scale sensitivity analysis for this sector is not currently available. However, for horticulture in general, produce quality is a primary issue and from a growers' perspective this means that pests and diseases are often seen as the dominant concern (see Risk N7), potentially in combination with water-related stresses (see survey results in Webster *et al.*, 2017). Concerns regarding produce quality are also related to high quality specifications demanded by major retailers as an assumed response to customer demand for unblemished food products. Quality issues also mean that increased irrigation needs are also a concern, especially in vulnerable crops such as Brassica that need consistent soil moisture, although this may be partly alleviated by increased use of covered systems (polytunnels etc.). In addition, for some crops, reduced times to reach maturity may be providing new opportunities for increased production by enabling multiple crops in a year, such as for lettuce and an increasing variety of baby leaf and salad crops (Armstrong, 2016).

Some crops or livestock-related produce are especially important for specific areas of the UK, including for non-food produce. For example, spring barley is the most important crop (by areal extent) in Scotland, with a high proportion of farm output used for malting barley (proportions vary from year to year due to the high-quality specifications for malting); most of the remaining output, usually lesser quality, is used for animal feed. In 2018, malt barley supply to Scotland's distilling and brewing sectors was impacted by both quality and yield issues due to drought, as noted by sector briefing reports. The drought also caused disruption due to low flow and higher water temperatures impacting fermentation, cooling and overall whisky quality (Fennell *et al.*, 2020), and at some distilleries production was halted for several weeks, these factors combining to have a significant effect (not presently unquantified) on one of Scotland's major export industries.

Hops are another crop with high importance for the drink industry and specific UK locations. Analysis of yields from hop cones based upon different types of weather modes (dry-cool, dry-hot, wet-cool and wet-hot) has shown longer and more severe drought and heat wave concurrences have increased more frequently than shorter concurrences with hot dry conditions especially associated with yield loss, including for major hop-growing regions such as Kent (SE England) (Potopová *et al.*, 2020).

Climate sensitivity is apparent not only for gross crop yields but also specific yields which represent the quality of produce, and which can be particularly important for food production. Regression analysis of wheat quality metrics that are especially used in bread production (specific weight; Hagberg Falling Number (HFN) as a measure of milling flour quality; and protein content) have found strong associations with weather conditions in preceding months (Pope *et al.*, 2019). Monthly sensitivity results depend on choice of metric but rainfall patterns in October, January, June and August appear especially important. Specific weight and HFN are strongly linked to summer rainfall,

with drier than normal conditions associated with increases in these metrics. Protein content appears to be sensitive to early frosts, late summer temperature maxima, and general conditions in December. However, Cammarano *et al.* (2019) found no discernible influence of yearly rainfall variations on malt barley quality at a specific site in Scotland. As already highlighted, fruit and vegetables also have known sensitivity to varying monthly and seasonal conditions, but again clear long-term climate-related trends are difficult to detect. This indicates the need for further research, including different crops and varieties, and metrics, including the wider implications of production shortfalls for domestic food supply (see 'Cross-cutting Risks' covered in section 3.7.1.5).

Although drought conditions have been less frequent in recent years (2018 being an exception), underlying exposure is increasingly evident. The UNSEEN methodology (see Chapter 1: Slingo, 2021) has been used to derive evidence that even within current climate conditions the entire UK wheat production area could be negatively affected by large-scale summer drought conditions in a single year, and because much of the current wheat production is concentrated in southern and eastern England, then when droughts do occur, they usually affect more than ~50% of the UK wheat cropping area as one contiguous cluster in those regions (Pope *et al.*, 2019).

Water availability for irrigation use is an important requirement for drier (predominantly eastern) locations of the UK to produce high-value crops of good quality (Hess *et al.*, 2020). Although the agriculture sector overall takes a small proportion of water supply, in some locations and catchments this is much higher and the seasonal water demand usually occurs at the driest time of year. Due to both increased soil moisture deficits and variability in summer rainfall, and demand for more water to maintain or improve the quality of produce, there are increased pressures for supplemental irrigation. These additional demands on water resources are most pronounced in water-stressed regions such as southern and eastern England, but have now extended to other regions, including eastern Scotland and eastern Wales, especially during drier summers, meaning the distinction between rain-fed and irrigation-fed areas has become less clear.

#### 3.7.1.1.3 Grassland and Livestock Production

In terms of evaluating grass as a crop, modelling of European-scale changes in grassland productivity for 1961-2010 has shown an increase of potential annual grassland production (over 3% per decade) of which 97% is attributed to increased CO<sub>2</sub> levels with 15% attributed to nitrogen deposition/fertilization and only a very small fraction to climate parameters (Chang *et al.*, 2015). This large-scale analysis showed that grassland productivity was higher in western regions of the UK, which facilitates higher livestock numbers in these locations. However, other management factors beyond the role of nitrogen fertilisation (which is included in the Chang *et al.* 2015 study through a rather simple parametrization scheme) play a role, therefore attribution of productivity to different factors may not be necessarily representative of all areas of the UK.

Regarding national-scale livestock production, other factors (notably markets and policy) tend to dominate at present. Livestock farming usually occurs in wetter areas of the UK which also typically experience more interannual seasonal variability, therefore this type of land use is typically more adaptable to changing conditions (although as discussed below, we know there are limits to this current adaptive capacity). As reported in CCRA2, at present only small, localised, effects on milk production have been noted, and in more marginal areas it is often the influence of cold weather in

winter and spring that can be the main limitation on grass production, which are most manifest during more extreme conditions in particular years. High temperatures in combination with intense solar radiation can cause heat stress resulting in a decrease in both forage intake (Hill and Wall, 2017) and production outputs (Hill and Wall, 2017; Van Laer *et al.*, 2015). In housed livestock systems, temperature events that are beyond the capacity of the ventilation system can result in increased energy and water use and an increased risk of disease (Skuce *et al.*, 2013). Also, livestock health (Amundson *et al.*, 2006) and welfare (Van Laer *et al.*, 2014) can be negatively impacted.

In addition to affecting availability for livestock fodder and bedding, variations in straw production can have a negative impact on the livestock sector, with impacts extending to following years. This occurred in 2017-18, including the effects of drought in many locations during summer 2018, with reduced availability and quality of straw causing farmers to source straw from further distances and at increased cost, and with the EU relaxing regulations to allow additional forage areas (Bell *et al.*, 2018; Salmoral *et al.*, 2020). During the same period, arable farmers had to plough in straw to complete autumn sowing causing increased prices, although price increases may also have been affected by increased use in bio-energy production and increased demand due to concerns over animal welfare (Bell *et al.*, 2018).

#### 3.7.1.1.4 Forestry

Similar inferences regarding both climate-related risk and opportunity may be derived for national-level productivity for the forestry sector, although rather more of the sector has a broader emphasis on multifunctionality rather than simple output measures such as timber production (productivity is also associated with other important functions such as carbon sequestration – see Risk N5). As reported by previous CCRA, although there is evidence of enhanced tree growth both from the UK and more widely across Europe, attribution of this to direct climate factors, notably temperature increase, is not conclusively established, due to concurrent increases in CO<sub>2</sub> fertilisation and N deposition (Lindner *et al.*, 2014). Forestry production may also be exposed to sporadic extreme events, notably from windthrow exposure during severe storms and tree mortality or loss of function due to droughts, but evidence remains limited as to whether these have an influence beyond local-scale effects. Hence, it is possible that the largest climate change related influence at present, at least for some species that are important for production purposes, is pests and pathogens (Risk N8); the relative influence of different risk factors is confounded as stress from one risk (e.g., drought) can then increase susceptibility to another risk (e.g., pests and diseases). This combination of risk factors therefore typically acts to limit our confidence in the attribution of individual factors in the absence of large-scale multivariate analysis.

#### 3.7.1.1.5 Flooding, Coastal Erosion and Wildfire Risks

Flood risk is a key hazard that impacts on land use decisions. Over 90,000ha of the best quality land (BMV/LCA) in the UK is at risk of coastal flooding and over 400,000 ha of this land is at risk of fluvial flooding, with significant geographic variations (based upon a 1 in 75-year event: Sayers *et al.*, 2020). A significant proportion of this land has been flooded in recent years, notably from fluvial flooding and especially on alluvial land on the floodplains of major rivers such as the Severn, Trent, Tay, Tweed, Tywi (Towi), Clwyd, and Lagan. By contrast, although still a continuing hazard, amounts of land lost to coastal erosion remain relatively small on an annual basis, although this land is of course

lost permanently, whereas flooded land may be eventually reclaimed and still be used, albeit often through a different use than originally intended. In England, coastal erosion of BMV land for 2005-2025 has been calculated at 74ha using a central estimate (50% confidence level) with an upper estimate of 98 ha (5% confidence level) based upon extrapolation of erosion rates through the National Coastal Erosion Risk Mapping (NCERM) project (Jacobs, 2018). Equivalent figures for other areas of the UK are thought to be lower but remain to be confirmed.

Available evidence suggests that wildfire may be an under-recognised risk with some research suggesting an increase in higher magnitude events when meteorological conditions are conducive (i.e., drier conditions often accompanied by warmer weather), although these conditions remain very episodic meaning trends are difficult to establish [see Box 3.1: Introduction]. There is currently more emphasis on this risk factor for forestry as compared to agricultural land but incidence data show both are at risk (Belcher *et al.*, 2021), although at present the risk magnitude is of high local importance rather than being a factor for overall national production levels in agriculture or forestry.

One major insurance firm (NFU Mutual) has reported that farm fire costs during the dry Summer 2018 for the UK were nearly £32m, an increase of 137% on 2017 with the overall costs of claims for farm fires over the harvest period up by 21% at £5.5m (Ecosulis and Farmlytics, 2019). Anecdotal reports from 2020 have suggested that harvesting during heatwave conditions has incurred a significantly elevated risk on stony ground due to generation of sparks, although quantitative data showing the relationship to actual wildfire events is yet to be produced. Further work is therefore required to show if there is a longer-term trend towards increasing wildfire events on agricultural land.

An important factor to consider is that extreme events often affect not only that year's agricultural production but also have implications, which can then affect following years. For example, planned winter crops may need to be abandoned and replaced by spring-sown crops if conditions allow, or sometimes an enforced fallow year may be required to re-establish favourable agronomic conditions.

Regarding the externalities from production activities, the combination of increased heavy rainfall and prevalence of agricultural practices that result in large areas of bare ground at critical periods (notably autumn) has been associated with severe soil erosion in some locations (Boardman *et al.*, 2017; Rickson *et al.*, 2019), as discussed further for Risk N4. Attribution between climate and management pressures is difficult and very likely to be spatially variable due to local factors, including an increased risk on steeper slopes. In addition, risks of soil structural degradation, notably from compaction, have climate-related and management components (i.e., trafficability and livestock access constraints on wetter soils) with evidence suggesting degradation has become widespread in some locations, notably on arable land (Lilly *et al.*, 2018; Royal Society, 2020; see also Risk N4).

### 3.7.1.2 Future risk and opportunity (N6)

#### 3.7.1.2.1 Climate exposure and sensitivity

In terms of incremental change, general agroclimatic indicators clearly show a trend for warmer temperatures throughout the year (e.g., Arnell and Freeman, 2021), implying new opportunities will further develop, including the potential for increased crop growth and livestock to be outdoors more during winter months. However, higher temperatures will also have an important influence in advancing crop phenology, this being either a risk or opportunity depending on crop/cultivar. In practice, a longer growing season may also be interrupted or curtailed by increasing risks due to soil wetness from wetter winters, especially on more vulnerable soils (e.g., gleys) that are poorly drained (also depending on condition of field drains). The growing season is also increasingly likely to be disrupted by drought or heat stress from projected trends towards higher maximum temperatures and reduced summer precipitation (Chapter 1: Slingo, 2021; Arnell and Freeman, 2021). It is also possible that an earlier start to the growing season increases early-season frost exposure for some crops and locations, notably for fruits (Unterberger *et al.*, 2018) although this combined risk requires further analysis in the UK. Future climate projections also indicate a continued increase in solar radiation during the growing season, which may potentially benefit enhanced photosynthesis and plant growth, but also contribute to increase evapotranspiration and water demand.

Both risks and opportunities are related to the type of farming or forestry, notably choice of crop, livestock or tree species (and specialist cultivars), and the spatial and temporal dimensions of the climate effects that correspond with different magnitudes of climate change. The interaction of multiple climate parameters with other biophysical and socioeconomic factors, including the current plans for Net-Zero GHG emissions, means future assessment inevitably involves some uncertainty although more evidence is now available than with CCRA2. Combined analysis of climate and socioeconomic scenarios has shown how land use decisions, whether primarily determined by productivity (notably for food security) or in a multifunctional context, together with the influence of drivers such as technology, commodity markets, or consumer preferences (e.g., changing diets) can result in very different outcomes regarding land use change and risks/opportunity related to long-term sustainability (e.g., Harrison *et al.*, 2016).

Regarding interactive soil-climate constraints, changes in field capacity duration (Figure 3.10) imply a reduced period during which soil wetness constraints prevail for many eastern locations in England and Wales, although remaining a major factor for land use decisions in the west and north (Barrow *et al.*, 2020; Keay, 2020); similar findings using UKCP09 data have been reported from Scotland (Brown, 2017). By contrast, as highlighted in CCRA2, future climate changes imply that soil moisture deficits will increase and become an increasing constraint on land capability and hence land use options, especially for eastern locations and on drought-prone soils. Furthermore, the new data from UKCP18 suggests that the relationship between warmer drier summers and increased soil moisture deficits will be stronger, although detailed analysis of the changing seasonal pattern of soil moisture for agriculture and forestry is still ongoing. In Wales, analysis of soil-climate constraints using UKCP18 has shown that, although drought risk is rather limited at present, it becomes a much stronger risk factor for a significant proportion of the country (Welsh border, Pembrokeshire, Anglesey and north Wales) by the 2050s, and especially by the 2080s period (Keay and Hannam,

2020). Drought risk constraints can be alleviated by supplemental irrigation, but this will require additional investment (which may not be cost-effective for some land uses) and, as discussed below, in some locations water availability is very likely to become an increased concern for land managers.

Changing seasonal soil moisture patterns may have further implications for land management in autumn and spring too, with an extension of drier soils from the summer potentially benefiting autumn activities (e.g., harvesting, sowing), whilst wetter winters may constrain the drying of soils in spring. Present assessment of evidence, including recent evidence from Wales (Barrow *et al.*, 2020), supports this inference, but there are considerable uncertainties, notably because the changes will strongly depend on soil water drainage/retention properties (including ongoing performance of artificial field drains), but also because autumn/spring climate projections are more inherently uncertain than summer/winter and that these are projections of long-term averages hence masking considerable year-to-year variability which also constrains land management options (cf. Brown and Castellazzi, 2015). An important issue to recognise therefore is that we currently have rather limited evidence regarding how interannual variability in seasonal conditions will change into the future, and this variability also has a significant influence on land use decisions, especially for arable agriculture because optimisation of production is based upon tightly-managed schedules. This includes the effects of changing spell lengths (notably duration of dry/wet periods through the growing season and its critical phases). Full investigation of variability-related risks and opportunities as derived from analysis of UKCP18 data has yet to be published.

As discussed further for soils (Risk N4), in addition to findings from UKCP18 (Chapter 1: Slingo, 2021), new evidence from ensemble modelling (Spinoni *et al.*, 2018) suggests an increase in drought frequency, notably for southern and eastern UK, and moderate increase in drought severity, notably for southern UK, with these changes becoming more pronounced with time (comparing the 2071-2100 period with the 2041-2070 period). This increase in drought frequency and possibly also severity has major implications for water availability for agriculture and potentially some forestry enterprises: the increase in local soil moisture deficits may mean some crops and land uses become unviable based upon current use of water resources.

CCRA2 identified how future climate change will have major implications for land capability. More recent analysis using UKCP18 with the ALC for England and Wales (Keay and Hannam, 2020; Keay, 2020) has provided further information, suggesting a reduced area of grades 1 and 2 (excellent quality and very good quality), with this land being downgraded primarily to grade 3a/3b (good quality and moderate quality) by 2050 and in some areas downgraded further to grade 4 (poor quality) by 2080 (all emissions scenarios). Inferences using an assumed 'medium' and 'high' emissions scenario also suggest that some land that is currently ALC 3a/3b will be downgraded to ALC 4 by 2080, particularly in the 'high' emissions scenario. This indicates that a significant proportion of existing good quality land would become marginal for arable uses, primarily based upon drought risk criteria. Similar findings for Scotland, regarding increased drought risk and land capability, were reported in CCRA2 (based upon UKCP09), although the risk in Scotland is projected to be proportionately smaller. No equivalent analysis for Northern Ireland on future changes in ALC has been completed to-date.

CCRA2 highlighted that changing future climate conditions imply that the distribution of crop and livestock production would be required to shift in response to changing land capability as a form of large-scale adaptation required to maintain production. Further research provides more support for these inferences. Using higher resolution climate modelling (1.5km scale) with a high climate change scenario (RCP8.5), Ritchie *et al.* (2019) found that summer drying by the end of this century (compared to a 1998-2008 baseline) could contribute to loss of suitability for arable land in eastern UK and an increase in the west. Moisture deficits in the east could potentially be alleviated by increased irrigation but under this scenario the magnitude of increased crop water demand would be very likely to exceed local supply with water resource zones in the south and east shown to become increasingly water-stressed with a larger supply-demand deficit.

#### 3.7.1.2.2 Arable and Horticulture Crops

These large-scale changes also have major implications for the relative geographic suitability of different crops. Suitability modelling of a wide range of crop species has been developed for Wales (Bell *et al.*, 2019) based upon UKCP18 data and related ALC biophysical indicator criteria showing that general trends in suitability change over time following a similar pattern for most crops between present day and 2080. This general pattern is for a decrease in suitable area for most species due to increased drought risk constraints, although the results are based upon no further adaptation (e.g., through genetic improvement programmes), and for some crops currently considered as novel or niche there may be opportunities (see Risk N9).

The underlying challenge of providing adequate water supplies to deliver production goals has been further emphasised by new results from the CCC Water Availability study (HR Wallingford, 2020). Using UKCP18, this study found a similar increase in the supply-demand deficit for water-stressed areas (most notably south and east England but also very likely to extend to other areas) compared to similar work for CCRA2 and that agricultural water availability would be ultimately constrained by decisions on environmental flow requirements in the future climate, especially for a 4°C world compared to a 2°C world. These findings are consistent with other evidence for reduced water availability. The probability of annual abstraction being close to the maximum licence limit has been shown to increase significantly when comparing baseline (1961–1990) and future (2071–2098, based upon UKCP09 data) periods in selected catchments, based on observed relationships between annual weather and irrigation abstraction in three licence usage groups (Rio *et al.*, 2018). In addition, the same study used river discharge thresholds as defined for mandatory drought restrictions to assess the annual probability of surface water abstraction restrictions. The annual probability of having less than 20% licence headroom in the highest usage group is projected to exceed 0.7 in 45% of the management units, mostly in south and east England, whereas in central and western England an increased risk of drought restrictions occurring was detected due to the lower buffering capacity of groundwater on river flows, with the annual probability of mandatory drought restrictions reaching up to 0.3 there in the future (2071–2098) period.

To complement the more general information on changing capability and suitability, new evidence is available on risks and opportunities for specific crops, and for livestock, including analysis at larger scales such as European level. Analysis of a series of climate metrics indicating damaging thresholds for UK winter wheat projects conditions for wheat production to remain favourable with heat stress remaining relatively low until 2050<sup>13</sup> although winter/spring waterlogging may become an increasing factor (Harkness *et al.*, 2020).

Similarly, Trnka *et al.* 2015 analysed a range of adverse weather indices for European wheat production (2081–2100 compared to 1981–2010), for different climate change projections. The main finding for the UK was the dominant effect to be field inaccessibility due to wetness. Although this only has an infrequent influence at present (ca. 1–5% risk in each year) for the main production areas of southern and eastern England, in the 2081–2100 period this risk increased in frequency (mainly a 5–10% risk for a model simulating 4°C global warming at the end of the century<sup>14</sup> or 10–25% risk for a model simulating 5°C global warming at the end of the century<sup>15</sup>; but smaller increases at less than 4°C global warming). However, the rest of the UK continued to experience increased frequency of wetness-related inaccessibility constraints in future, meaning shifting wheat production to new areas as suggested above based on decreased summer water availability may be constrained by wetness factors from increased winter precipitation. Phenological and agroclimatic modelling applied to climate projections reaching 2°C, 3°C, 4°C and 5°C global warming at the end of the century<sup>16</sup> suggest conditions may remain generally favourable for oil seed rape (Pullens *et al.*, 2019). However, significant uncertainties and knowledge gaps remain, and climate change analysis

---

<sup>13</sup> On pathways to between 1.7°C and 5.4°C global warming by 2100, projected by the CMIP5 ensemble driven with the RCP4.5 and RCP8.5 concentration pathways

<sup>14</sup> The GISS climate model driven with the RCP8.5 concentrations pathway

<sup>15</sup> The HadGEM2-ES climate model driven with the RCP8.5 concentrations pathway

<sup>16</sup> GISS and HadGEM2-ES driven with the RCP4.5 and RCP8.5 concentration pathways

has not yet considered the full interaction of different climate and non-climate parameters, despite advances in use of ensemble modelling (multiple climate and crop models) (Martre *et al.*, 2015; Rodríguez *et al.*, 2019).

Regarding drought risk, and specifically its influence on UK wheat yields, although the evidence indicates an increased risk, there remains significant uncertainty on the magnitude of this risk. Analysis by Clarke *et al.* (2021) has shown that modelling results based upon response functions derived using drought severity indicators are rather dependent on the indicators used, especially when the interacting effects of changing crop calendars and CO<sub>2</sub> fertilisation effects on yield are not incorporated, highlighting the need for a more integrated assessment including ecophysiological feedbacks with soil moisture deficits.

A key issue remains the interaction of changing CO<sub>2</sub> concentrations with other parameters. Recent, European-scale analysis for 1.5°C and 2°C global warming for a range of crops suggests that negative productivity effects from climate change may be partially offset by productivity gains from elevated CO<sub>2</sub> (Hristov *et al.*, 2020). However, the results are very sensitive to the assumptions used, including management factors, crop or cultivar, and spatial and temporal variations in the interacting variables (including soil properties and interannual seasonal variations) based upon the assumed crop growing area. This is especially applicable to assumptions regarding nitrogen timing and method of application in the context of prevailing weather conditions, and hence N accessibility to crops and implications for yield.

Regarding wheat yield quality, work from other countries continues to show that elevated CO<sub>2</sub> levels may have important implications, notably through reduced N and protein content but potentially also other nutritional values such as Zn content (e.g., Verillo *et al.*, 2017). However, these country analogues may not be directly applicable to UK. Furthermore, model analysis suggests that managed genotypic adaptation may maintain or even enhance wheat protein concentration (Asseng *et al.*, 2019).

#### 3.7.1.2.3 Grasslands and Livestock Production

For grasslands, recent analysis supports previous CCRA2 assertions of a longer growing season that may be constrained by soil wetness factors in west and north UK regions (Phelan *et al.*, 2016), although, as shown by analysis in England, Wales and Scotland, the period of maximum wetness (field capacity) may shorten depending on assumptions regarding field drainage system maintenance (Brown, 2017; Barrow *et al.*, 2020). Analysis using UKCP09 low and medium emission scenarios for 2050 (compared to 1961-90 baseline) using a metamodel approach indicates increased GB productivity for rotational and permanent improved grassland (ca. 25% and 10% respectively) but not for rough (unimproved) grassland (Qi *et al.*, 2018). Together with improved management (notably N use efficiency) these productivity gains may provide enhanced capacity for land sparing as assumed under the Net Zero GHG scenario. There is also some evidence, as noted above regarding the present climate, that elevated CO<sub>2</sub> may benefit grassland productivity. However, future climate changes towards higher temperatures and a general increase in summer soil moisture deficits, as noted above, may also affect species composition of the sward, quality of grass and other forages (Abdelgawad *et al.*, 2014; Lee *et al.*, 2017; Dellar *et al.*, 2018). This has implications for livestock

productivity and potentially for CH<sub>4</sub> emissions from livestock due to forages becoming more fibrous and of decreased nutritive quality with a lower nitrogen concentration.

Livestock are also likely to be directly affected by projected increases in temperature, especially when combined with humidity. The Thermal Humidity Index (THI) defines suboptimal and critical threshold levels of high temperature and humidity which cause stress in livestock, therefore affecting productivity (Dunn *et al.*, 2014). These limits are currently more of a productivity issue for other countries with a warmer climate than the UK but if projected future temperature increases are also accompanied by periods of higher humidity, this will increase the frequency of 'suboptimal' and possibly even 'critical' conditions. Analysis by the CCC Thresholds project (Jones *et al.*, 2020) of climate risk factors for milk production using the temperature component of the THI index and a very rapid global warming pathway to 4°C in the 2060s<sup>17</sup> projects that suboptimal conditions would become more frequent in southern and eastern England by 2050, assuming humidity levels remain similar to present. This is a low-likelihood, high-impact scenario, but the impacts may also represent those of an equivalent level of global warming reached at a later date (see Chapter 2: Watkiss and Betts, 2021). Analysis by Fodor *et al.* (2018) using the UKCP09 11-member PPE has generally indicated low average annual milk production losses from the THI relationship, but with considerable interannual variability, with the hotter locations projected to show an annual milk loss exceeding 1300 kg/cow by the 2090s (ca. 17% of today's productive capacity). In order to address some of the key uncertainties, this study also developed a more biologically-appropriate model and concluded that SW England is the region most vulnerable to climate change economically because of the combination of high heat stress with high dairy herd density, such that income loss for this region by the end of this century may reach £13.4m in average years and £33.8m in extreme years (regional farmgate milk production was £0.77bn in 2016, and when processed for dairy produce at £2.27bn). In the most affected regions, heat stress-related annual income losses for average size dairy farms were estimated at £2000-£6000 for average years and £6000-£14000 for extreme years. In addition, by the end of the century, it was also inferred that dairy cattle in large portions of Scotland and Northern Ireland will experience the same level of heat stress as cattle in southern England today. These general findings have also been confirmed using the more detailed 12km spatial ensemble data from UKCP18 which found that, based upon dairy farming remaining in its present locations, the area of greatest risk now and in the future would be south-west England (increases in heat stress of up to 60 days per year by 2070 compared to the baseline using RCP8.5 scenario), followed by Wales, the Midlands and northern England (Garry *et al.*, 2021). The same analysis found increases of less than 15 days across much of Northern Ireland and Scotland.

Climate change will also be likely to influence the productivity (and therefore supply) of bioenergy crops, with modelling capability for these species now also being improved (Littleton *et al.*, 2020). According to Defra census data around 129,000 hectares of agricultural land were used to grow crops for bioenergy in the UK in 2017, representing just over 2% of all arable land in the UK. Future warming-related increases in accumulated degree days are expected to increase growth rates and productivity of these crops, although in drier locations increases in soil moisture deficits are also very likely to affect growth potential, especially as these crops have high water demands. Warming will also mean that some crops such as poplar and miscanthus will also have a greater extent of land

---

<sup>17</sup> UKCP18 regional projections driven by a global model with the RCP8.5 emissions scenario

with appropriate climatic suitability in the next few decades, providing opportunities for expansion including potentially into current marginal land.

#### 3.7.1.2.4 Forestry

In forestry, as discussed in detail in previous CCRA, projected increases in drought risk have important implications for some commercially important species, notably Sitka spruce. In Wales, tree suitability analysis has been conducted similar to the crop suitability analysis referred to above, focusing on Sitka spruce and sessile oak. This also shows a declining suitable area for commercial production due to increased drought risk, although this does not preclude trees being grown for non-production purposes, including for ecosystem services such as flood mitigation, carbon storage, and supporting biodiversity (Bell *et al.*, 2020). Alternatively, commercial production may adapt to increased drought risk by developing a long-term planting strategy that focuses on tree species that are more resilient than the 2 indicator species used for the analysis, although this has not occurred yet.

Recent analysis has also aimed to quantify risks to current timber production in Scotland using a scenario reaching approximately 5°C global warming at the end of the century<sup>18</sup>, as modelled over a 50-year rotation using the Ecological Site Classification (ESC) (Davies *et al.*, 2020). This projects Sitka spruce to continue to maintain an economically viable production level over most of Scotland but increased drought risk in some regions, notably central and eastern Scotland, implies that higher drought tolerance of alternative species will mean they have competitive advantages. This finding would support an increased emphasis on species diversification strategies that also have other co-benefits (e.g., for biodiversity and as resilience against pests/pathogens).

To a varying degree, trees have evolved with relatively high levels of phenotypic plasticity in order to tolerate environmental changes in situ over their long lifetimes, and this will confer some additional resilience whilst genetic adaptation through natural selection occurs over the longer time taken for generational turnover. However, new evidence also suggests that there may be limits to this acclimation when repeated extreme droughts occur, which would be consistent with increased future drought frequency in UKCP18 (see Chapter 1: Slingo, 2021). These repeated droughts may have a more pronounced effect on tree productivity and mortality because subsequent droughts apparently have a greater impact than the initial drought event, especially for conifers, and therefore that acclimation is limited (Anderegg *et al.*, 2020).

However, as highlighted throughout this evaluation, multiple factors act together to influence water-use efficiency (WUE) in plants and hence drought risk, including also changes in CO<sub>2</sub> and atmospheric deposition of N and S pollutants. Large-scale analysis of CO<sub>2</sub> fertilisation effects suggest annual biomass increments could increase by 15-25% by 2050 (e.g., Terrer *et al.*, 2019) but this will also be strongly dependent on local factors that influence nutrient availability, WUE, and drought sensitivity. Recent analysis has investigated changes in these factors for four tree species in twelve forests across climate and atmospheric deposition gradients in Britain (Guerrieri *et al.*, 2020)

---

<sup>18</sup> SRES A1FI scenario

showing considerable variation in WUE due to interactions between climate and atmospheric drivers (for oak and Scots pine), but also variations due to an age effect (for Sitka spruce). Increase in WUE was mostly associated with increase in temperature and decrease in moisture conditions across the GB north-south gradient when interpreted over a 30-year period, and this appeared to dominate over the atmospheric deposition effect, although forest stand age was a confounding factor especially for Sitka spruce.

#### 3.7.1.2.5 Flooding, Erosion and Wildfire Risks

Regarding extreme events, future climate projections imply increased risks from both fluvial flooding and coastal flooding to agricultural land (Sayers *et al.*, 2020) when analysed over a period of years as represented by the extent of flood risk for land currently defined in planning systems as best quality (therefore not yet including future projections of changing land capability as described above). These findings imply increased risks for agricultural productivity during the individual years when flooding prevails, although changes in flood frequency will be the critical factor. These results also suggest that the projected magnitude of flood risk has increased since similar work for CCRA2 (although methodological variations should also be noted). For coastal flooding, the increased risks are more manifest for England (apparently very little change for Scotland and Northern Ireland), whereas for fluvial flooding significantly increased risks are highlighted for all countries but with the highest changes in risk for Wales. The increase in risk is more pronounced for a pathway to 4°C global warming in 2100 compared to 2°C.

These results are based upon land affected by a major flood event (1 in 75-year event) and further work to investigate changes in the frequency and extent of flooding together, including for smaller-scale localised events, will also be required because it is the frequency of flooding that influences land use decisions for a particular parcel of land. Also, the season when flooding occurs can be critical, with some land uses (e.g., grassland) often less sensitive to winter fluvial flooding. Coastal flooding usually has more severe ramifications as saline intrusion necessitates expensive land remediation activities to restore production. In addition, although Sayers *et al.* (2020) have investigated changes in surface water flooding risk, further analysis is required to ensure applicability to agricultural land because this needs to include the key role of agricultural drainage with regard to spatial and temporal changes in the water table.

A further issue is that as sea levels rise, some low-lying catchments that are currently drained by an effective elevational gradient to the sea (i.e., by gravity) will need to be pumped with increasing frequency. Similarly, those catchments that already require the assistance of pumped drainage will require additional pumping capacity. In some catchments, an increase in river flows in combination with sea-level rise will provide an additional compound risk for drainage infrastructure.

**Table 3.17** Increased area of current best quality agricultural land at risk of major flooding (1 in 75-year return period) assuming no further adaptation (i) coastal (ii) fluvial (Source: Sayers *et al.*, 2020)**i) Coastal**

Assets at significant risk	Baseline (Ha)	2050s on a pathway to +2°C in 2100	2080s on a pathway to +2°C in 2100	2050s on a pathway to +4°C in 2100	2080s on a pathway to +4°C in 2100

BMV land N. Ireland	3,442	10%	18%	22%	37%

BMV land permanently lost to future coastal erosion has also been projected for England using extrapolation of NCERM data (Jacobs, 2018). For the 2050s, a central estimate (50% confidence level) of 240ha lost has been derived with an upper estimate (5% confidence level) of 320 ha. Equivalent estimates for 2100 are 545ha (central) and 754ha (upper), or if the erosion and movement of complex cliff landforms are included, year 2100 estimates would be 550ha (central) or 1450ha (upper) (Jacobs, 2018). Equivalent data for the rest of the UK have not been available but are provisionally assumed to be smaller due to the lesser quantity of equivalent higher quality agricultural land.

For wildfire risk, the current evidence suggests that risk magnitude increases broadly in line with increased temperature change over time and therefore is greater for higher climate change scenarios (i.e., greater for 4°C global warming compared to 2°C) (Belcher *et al.*, 2021). In terms of vulnerability, wildfire may be a more notable risk for forestry when compared to agriculture,

although the greatest increases in risk exposure are indicated for southern England where agricultural productivity is the dominant land use as compared to the northern UK where most of the land used for forest production services is situated.

#### 3.7.1.2.6 Knowledge Gaps

Collectively, assessment for this topic shows that the quality of evidence has improved since CCRA2. This includes new studies using high resolution climate models that better represent extremes (e.g., Ritchie *et al.*, 2019) although limitations remain in understanding how different types of adverse event affect crop yields, especially when using monthly data (see Falloon *et al.* 2014; Franke *et al.*, 2019, 2020). Inter-comparison programmes (e.g., Agricultural Models Intercomparison Project-AGMIP; Modelling Agriculture with Climate Change for Food Security — MACSUR) represent important advances in understanding capability of different models but are still constrained by differences in methods, assumptions and datasets etc. Much of the existing modelling work also does not fully include the interacting effects of increased CO<sub>2</sub> with climate change parameters or its interaction with water use efficiency and N uptake. Therefore, our assessment recognises that considerable uncertainty remains regarding how much potential yield gains from elevated CO<sub>2</sub> and enhanced photosynthesis productivity will be offset by climate-related deficiencies such as water stress and heat stress. We also have limited information on combined effects with other air quality parameters (e.g., changes in ozone (O<sub>3</sub>) concentrations). Regarding yield quality, there is some experimental evidence that elevated CO<sub>2</sub> will reduce grain protein concentration and gluten protein concentration, and therefore bread quality (Fernando *et al.*, 2015), but more evidence is needed on this topic (changes would be expected to also be strongly influenced by cultivar, and the timing and quantity of applied nitrogen in addition to CO<sub>2</sub> concentration). In addition, evidence suggests existing crop models are better at simulating water stress impacts than water surplus effects (nitrogen losses, diseases, anoxia, harvest conditions) (Lecerf *et al.*, 2019).

Finally, it should be noted that a production-related risk for which there is currently limited information is post-harvest storage of produce. Increased temperatures and related issues with moisture or humidity may have implications for the effective storage of different agricultural or forestry outputs, especially for the more sensitive crops (e.g., potatoes). This may be further exacerbated if the crop is already of reduced quality when harvested, and then storage may lead to further deterioration, thereby potentially reducing effective storage times for some produce unless additional investment in enhanced storage facilities occurs. Further investigation would therefore be beneficial on this topic, such as through methodologies that explore changes in storage degree days above defined thresholds for specific crops (both with and without further adaptation).

#### 3.7.1.3 Lock-in (N6)

Land allocation and management decisions often show considerable inertia and therefore can be slow to change in response to changing drivers. In addition, some socioeconomic drivers can encourage a continuation of existing practices in contradiction of requirements to adapt to a changing climate. This leads to a form of path dependency where present and future decisions can still be strongly influenced by the past, which can lead to a lock-in risk such that the pattern of land use remains a product of historic drivers rather than present conditions. For example, past trends

have seen a shift away from mixed agriculture and towards more specialisation and less diversification in both farming and forestry (Food, Farming & Countryside Commission, 2021). Also, plant breeding has produced greater yields but with a greater reliance on artificial fertilisers to supply nitrogen and other key minerals. These path dependencies may therefore act as a risk amplifier as climate change continues to diverge from the climates of the past. The risk is hence that productivity is additionally compromised by continuation of past land use decisions when a transition towards new and sustainable production systems should be occurring. Furthermore, these underlying socioeconomic factors that reinforce a continuation of past decisions may also be a contributory factor towards negative impacts for environmental quality.

The reasons for this inertia and lock-in require further analysis but are typically associated with access to machinery and equipment as well as knowledge and skills, together with the role of culture and traditional practices. To address these issues will require improved outreach and knowledge exchange in addition to funding support for capital assets, potentially also including new technology.

The longer lifetimes involved with forestry would imply a distinctively high potential for lock-in risks, hence the greater need, and often increasing awareness for anticipatory planning that includes a different future climate. The challenge for the forestry sector is then how and when to put this anticipatory approach into existing practices, as related to key decisions on stand management and rotation lengths before harvest. In reality, harvest cycles and production figures often differ from optimised projections as represented by planning through notional yield classes for tree species and location.

#### 3.7.1.4 Thresholds (N6)

Plant physiological and productivity thresholds related to bioclimate factors have been investigated for many years in agriculture and forestry as a key influence on species selection and therefore land allocation. For example, classic papers on crop physiology have shown the importance of the minimum water content required in the grain for wheat germination (35- 45%), which is related to the seasonal climate moisture balance, and exponential relationships between growth in cereals and absorbed solar radiation (Gallagher *et al.*, 1976; Gallagher and Biscoe, 1978). This has facilitated interpretation of yield to climate parameter relationships for different crops, including the familiar 5.5°C minimum threshold for grass growth used in standard growing season metrics. (e.g., as recommended by the UN FAO). Thresholds are therefore incorporated in planning tools such as for land capability classification and the ecological site classification for forestry decision-making based upon associations with physiology and plant performance (using metrics and thresholds for growing degree days, moisture balance, wind exposure, frost days etc.).

Regarding frequency of extreme conditions, the CCC Thresholds project (Jones *et al.*, 2020) investigated heat stress in winter wheat using projected changes in maximum temperature (3 consecutive days exceeding threshold 35°C during grain-filling, which presently occurs during July). Although this threshold is not exceeded at present or for a global +2°C change when following a RCP8.5 scenario, it is exceeded in a +4°C world where the threshold is exceeded for around 3-8 days/decade in the Midlands and SE England, which are both important wheat-growing areas. The same study also analysed the implications of heat stress in dairy cattle and the implications for milk

production using the temperature-based component of the established thermal humidity index, again finding a significantly increased risk of suboptimal conditions by 2050 with the RCP8.5 scenario. However, as highlighted above, temperature-based thresholds are often complex and will not occur in isolation and therefore effects are difficult to capture through simple indices (cf. Siebert *et al.*, 2017). For example, with winter wheat yield, moisture also typically becomes a critical risk factor at higher temperatures, or for dairy cattle and milk production, humidity interacts with temperature to determine stress levels. This interaction of multiple variables in a changing climate makes identifying discrete thresholds more difficult to identify with certainty for use in adaptation planning.

Further work is therefore required on heat stress, including the key role of humidity. Analysis by Kennedy-Asser *et al.* (2021) using both UKCP18 and CMIP5 climate models, has shown that model error in capturing characteristics of extreme heat generally reduces when using heat stress metrics with a larger vapour pressure component, such as simplified wet bulb global temperature (sWBGT). Similarly, other metrics, such as those based upon enthalpy, have been identified as more biophysically realistic in understanding heat stress for livestock, including in indoor settings (de Castro Júnior and da Silva, 2021).

A more multivariate approach to threshold analysis was used by Jones *et al.* (2020) to investigate implications for woodland productivity, in this case using a climatic moisture deficit (CMD) index to reflect the maximum accumulated monthly excess of evaporation over rainfall each year, and hence drought risk. This analysis used CMD thresholds of 200 mm for drought sensitive species (e.g., Sitka spruce, sycamore) and 300 mm for more drought tolerant species (e.g., Scots pine, Douglas-fir, oak, sycamore, hornbeam). Impacts on oak and beech were projected to be severe in a RCP8.5 high-end climate scenario (using a single model run), along with other deciduous woodland species. Impacts on conifers were mixed. All impacts vary geographically and were found greater in the south and east of the UK (including eastern and southern Scotland), affecting growth and timber quality, and are consistent with other analyses reported in this assessment on the effects of increased drought risk.

#### 3.7.1.5 Cross-cutting risks and inter-dependencies (N6)

Production is very dependent on water availability and soil fertility, both of which are declining resources in many areas of the UK and further influenced by climate change (for soils, see also Risk N4). Reduced water availability may mean irrigation for intensive agricultural and horticultural production will be in conflict with other water uses (including the needs of wetlands and freshwater biodiversity). Averting these water-related conflicts will require further development of improved abstraction and irrigation techniques, together with facilities for water storage to make more use of excess winter rainfall (including design features to avoid risks to water quality from overflow or other runoff). Especially in specialised horticulture, water efficiency gains may be also achieved by recycling of water and improved design of glasshouses or other types of cover (polytunnels etc.), but some designs may be detrimental to soil quality, and each will require further investment. In addition, maximising sustainable use of water resources in water-stressed areas will require enhanced collaboration, not just in the agricultural sector but with the wider range of users, in order to ensure resources are available at the most crucial times (Knox *et al.*, 2018).

Evidence also suggests that in a business-as-usual scenario, climate change will have further negative effects on the externalities associated with intensive agricultural production (e.g., Royal Society, 2020; Food, Farming & Countryside Commission, 2021). In addition to pressures for agricultural intensification, including 'land sparing' objectives associated with the Net Zero agenda (see below), similar indirect pressure to optimise production in specific locations may occur due to biodiversity objectives and allocation of a greater land proportion for protected conservation areas (e.g., nature recovery areas).

In the absence of improved practices, increased rainfall intensity and storm runoff will interact to increase the risk from excess nitrogen (N), phosphorus (P) and pesticide losses that are not taken up by plants, impacting on soil quality, water quality and climate change mitigation efforts (CO<sub>2</sub> and N<sub>2</sub>O emissions) (Arnell *et al.*, 2015; Lu *et al.*, 2017). Risk is greatest when application is associated with saturated soils or periods of high rainfall or when a large proportion of bare ground is exposed to surface runoff. Sediment loads from episodes of severe soil erosion during extreme rainfall events can also be a problem for water quality. Increased volatilization of ammonia fertiliser from higher evapotranspiration rates may also affect air quality and atmospheric emissions targets, although evidence is limited here.

Analysis of water quality interactions shows results are strongly influenced by assumed interactions between climate and land use change. Based upon an assumption of optimised land use that in a warmer drier climate would lead to a shift from arable to grassland in the Thames basin, analysis at 2 locations has suggested reductions in N concentrations but increase in P concentrations (Bussi *et al.*, 2017). Similarly, analysis in the Wensum, Avon and Eden catchments using high-resolution climate modelling and the UKCP09 weather generator has shown average winter P loads could increase up to 30% by 2050s, as exacerbated by agricultural intensification and will be limited only by large-scale agricultural changes (e.g., 20–80% reduction in P inputs) (Ockenden *et al.*, 2017).

Negative impacts on water quality may also become an increasing concern for irrigation supplies. As future summer river flows are projected to decline, reducing the dilution of pollutants and impacting on water quality (see Risk N11), then pathogen or other contamination of irrigation water may become a greater problem than present. Increased pollution of groundwater sources may also occur (e.g., from pesticides or nitrates), although evidence here is limited. Public health implications may become especially severe in some locations where high-value crops are grown, notably where land use is currently optimised for unprocessed 'ready to eat' produce including salads.

The projected trend towards increasing frequency of wetter winters combined with further agricultural intensification, including use of heavy machinery, indicates further risks from soil compaction unless precautionary measures are taken. Recent trends towards heavier agricultural machinery can cause increased pressures on soil resources, unless used only at appropriate times (Keller *et al.*, 2019). Compaction can affect yield and damage soil structure (e.g., reduced grass yields: Hargreaves *et al.*, 2019) whilst also causing increased flood risk (Alaoui *et al.*, 2019), nutrient runoff and water quality and N<sub>2</sub>O emissions through denitrification. As optimised agricultural production following current practices usually requires land has good drainage (both for access and for crop growth), field drainage systems are used to remove excess water but, in addition to causing

water quality problems, this can also contribute to increased flood risk downstream in some catchments (depending on drainage system and soil properties).

Pests, pathogens, and INNS (Risks N7 and N8) have important interactions with productivity in agriculture and forestry, both directly and indirectly. In some instances, these may have detrimental impacts on pollinators which are an essential requirement in the production of some crops (Vanbergen *et al.*, 2014, 2018). Both agricultural and forestry production systems can also have a large influence on landscape character (Risk N18), either positively or negatively. These wider implications will depend on whether changes in production systems (both for climate change adaptation and mitigation) are also developed in sympathetic accord with their wider landscape context.

There are also important interactions with other CCRA chapters. Farming and forestry are integral to a wide diversity of rural communities across the UK and those working on the land may have increased exposure to some climate-related health risks (Chapter 5: Kovats and Brisley, 2021). Cultural heritage associated with traditional agricultural/forestry practices are important to recognise in developing responses that protect both the natural environment and cultural heritage. In addition, negative impacts on productivity can have severe consequences for agriculture and forestry businesses, and associated sectors, notably in food and drink processing (Chapter 6: Surminski, 2021). Perception of these risks, notably relating to the impacts of changes in water availability, are variable across supply chain despite affecting not only growers (who are more directly exposed) but also others including packers, manufacturers, and wholesalers, which may further compromise the resilience of the whole chain (Zurek *et al.*, 2020).

Extreme weather can have further severe impacts on the full agricultural and food/drink supply chain to then affect the consumer. Following on from the negative effects of cold spring weather, then summer drought and heatwave in 2018, it was reported that between March and July, the UK wholesale farm-gate prices of the following commodities increased significantly: onions (+41%); carrots (+80%); lettuce (+61%); wheat for bread (+20%); strawberries (+28%); the average increased cost to the consumer was estimated at £7.15/month/household (Centre for Economics and Business Research, 2018).

Furthermore, implications of reduced productivity for domestic food supply can have consequences in terms of food security issues, especially in vulnerable communities, and therefore disruptions to food supply can have important implications for human health and policies to address societal inequalities (Chapter 5, Risk H9: Kovats and Brisley, 2021). Here there is also an important interaction between the domestic food supply and the changing pattern of international food supply (Chapter 7, Risks ID1, ID2: Challinor and Benton, 2021), with reduced supply of key food commodities associated with price rises and a further exacerbation of food poverty issues for vulnerable people and communities. Finally, agricultural production at present usually relies on local water supplies but a future shift towards increased agri-tech and large-scale intensified production systems will very likely mean it is increasingly reliant on utility networks and associated infrastructure which can be at risk of severe disruption, especially following extreme events (Chapter 4: Jaroszewski, Wood and Chapman, 2021)). These challenges for agriculture are further exacerbated because the UK

population is increasing (an additional 10 million people by 2050 following a central projection) and therefore more food will be required either from domestic or overseas sources

Regarding incomes in farming or forestry, reduced crop yields or impacts on the quality of livestock or timber produce can obviously be severely detrimental. However, the linkages are complex due to the influence of other factors, including markets and policy. For example, if crop yields are reduced on a large scale at international level, then global prices increase and an arable farmer may obtain a good economic return even with a limited farm output for that year, although a livestock farmer may face increased input feed costs. For example, the Russian grain export ban of 2010, which was a consequence of the effects of the extreme heatwave of that year on the grain harvest in that region, acted to increase global grain prices and make them rather more volatile.

### 3.7.1.6 Implications of Net Zero (N6)

The CCC (2020) Net Zero 2050 scenario pathways are predicated on crop yield improvement (through improved agronomy and crop breeding) and land sparing to enable additional C sequestration through afforestation and bioenergy crops. Assumptions on future crop yield improvement may be challenged by the climate-related risks to present and future production that have been described above. Hence, although the Net Zero scenario assumes climate-resilient crops are developed such that average UK yield gains increase by ca. 30% by 2050 compared to present (based upon an increase of wheat yields to 11t/ha compared to present 5-year average of 8.4t/ha), this does not fully recognise yet the considerable inter-annual variability in yield that presently occurs due to climate factors, including years such as 2018 and 2020 when yields were considerably reduced (each for different reasons). In addition, crop production areas show considerable variability from year to year as farmers adjust to the past year and prevailing conditions; this adjustment would be rather more constrained if overall production areas were reduced.

Furthermore, Net Zero assumptions based upon following an optimised land sparing pathway, in terms of land allocation objectives, are very likely to be affected by changing land capability throughout the UK, especially from eastern regions becoming drier (consistent with findings from UKCP18), and difficulties with yield stability due to both changes in the long-term climate and its interannual variability. These ongoing effects of climate change will therefore present a considerable challenge for delivery of the Net Zero goal. The default assumption in development of the CCC (2020) Net Zero scenarios to-date has been optimal adaptation to enhance production outputs; further work is now in progress to re-evaluate these assumptions as would be consistent with the assessment presented here. The challenge for crop breeding is to develop cultivars that can increase yields whilst also being resilient to the wide range of climate-related effects that can occur in the UK, including heat stress, drought risk, wetness factors (e.g., lodging), and pests and pathogens (see Risk N7), rather than just one of these factors in isolation.

In addition, most of the land use or land management options identified as likely to be beneficial for contributing to Net Zero, such as a shift towards higher stocking densities on permanent grassland or high sugar grasses for livestock forage, have yet to be fully investigated in terms of whether they will be also a robust option based upon future climate projections. Higher livestock densities on

grassland may have negative outcomes for soil degradation and water quality, especially in the context of more intense rainfall events and soil saturation or infiltration constraints (as associated with soil compaction), unless carefully managed. For forestry production (and associated carbon storage), if new woodland is targeted to be planted on land with high suitability, rather than land that is less suited for agriculture as occurs primarily at present, then there could be important benefits for achieving the Net Zero goal as this is likely to enhance production and carbon storage (unless occurring in locations susceptible to drought risk).

These interactions between a changing climate and agricultural or forest productivity have implications for previous studies that have attempted to 'optimise' production in specific locations. For example, optimisation studies for bioenergy crops in the context of Bioenergy with Carbon Capture and Storage (BECCS) schemes (e.g., Donnison *et al.*, 2020) require further investigation because they have not considered the additional adaptation requirements that may be required in the future, notably due to water availability.

Research is now further exploring synergies and conflicts between production goals and Net Zero. For example, yield and production changes for UK spring barley and hence supplies of malting barley have been investigated using UKCP09 weather generator data for the 2030s-2050s (Yawson *et al.*, 2018, 2020). Future land area available for barley production was defined pro rata from projected changes in agricultural areas assumed by the CCC central Net Zero GHG scenario. Although yields showed potential future increases due to climate warming and increased CO<sub>2</sub> concentrations, reduced available land area following Net Zero pathways meant that a production supply deficit for malting barley was estimated based upon continuation of current demand (especially from the drinks industry). Similarly, the CCC Balanced Scenario for Net Zero assumes average wheat yields increase ca. 30% to reach 11t/ha by 2050 (with other crops also showing similar gains) in order that the production area can be decreased, but as noted above crop yields have been rather variable in recent years with wheat yields in 2020 reduced by 17% at 7t/ha due primarily to climate factors. The CCC (2020) Net Zero report recognises that average yields have also tended to reach a plateau level after major gains towards the end of the 20<sup>th</sup> century. Therefore, if the cereal cropping area was reduced consistent with the same CCC Net Zero scenario, as required to spare land for bioenergy crops and new woodlands, then following current yield trends this would imply a significant production shortfall with potential further implications for domestic food supply. By contrast, allowing an increased cropping area to allow domestic food supply to have headroom to adjust to current patterns of yield volatility would require a greater emphasis and reliance on other innovations to meet the Net Zero goal such as Carbon Capture and Storage. The current focus on average yields in Net Zero scenarios is therefore yet to recognise that the average disguises considerable underlying interannual volatility which agricultural systems adjust for by varying crop production areas as a risk compensation measure.

The CCC (2020) Net Zero scenarios additionally assume improved productivity of conifer plantations (in terms of yield classes and carbon storage) which in our view seems realistic, at least in the medium-term. However, identifying suitable land for large-scale woodland expansion to deliver additional carbon sequestration as a key component of the Net Zero scenario will also require an adaptive approach (as currently under investigation by the CCC). For example, tree suitability modelling of new planting opportunities for sessile oak and Sitka spruce in Wales has found that

meeting the 152,000 ha target of additional woodland by 2050 in the context of protecting best quality agricultural land is only achievable through using land that is less biophysically suited, especially considering future climate change, or that different species may be required (Bell et al., 2020).

Finally, changes in demand driven by the Net Zero agenda could also have major implications for domestic production and the capacity to meet that demand. For example, a shift from a meat-dominated diet to a more vegetable-based diet may lead to requirements for increased cropping and in turn, irrigation demand. However, as a significant proportion of existing crops are used for animal feed, then more direct use of crops to supply human nutritional needs can potentially provide increased efficiency in land use compared to existing patterns. This would still require that the land used for cropping could consistently provide high-quality nutritious produce; as noted above, at present there are often considerable interannual variations in the quality of produce as well as quantity (with lesser quality produce often used as animal feed).

#### 3.7.1.7 Inequalities (N6)

As described above, the impact of adverse weather on reduced production can have serious consequences for livelihoods, especially in rural areas. This can act to exacerbate societal inequalities, including for occupational categories such as tenant farmers or seasonal workers (farming, horticulture, or forestry) that often have limited security or capital reserves. As also noted, the impacts of reduced agricultural production on domestic food supply can have important implications in terms of food availability and price, which can be especially severe for people on limited incomes.

Beyond these general inferences for those directly involved with the sector, there is currently no specific evidence for how societal inequalities may be affected by climate change risks and opportunities for agricultural and forestry productivity, although any resultant impacts on food availability and food price will obviously be a key concern.

#### 3.7.1.8 Magnitude scores (N6)

Magnitude categories (Table 3.18) are based on expert judgement of expected climate change impacts (risk and opportunity) across the full range of production outputs, as supported with quantitative evidence for some of these outputs (yields and national productivity etc.), but excluding impacts of pests, pathogens and INNS. The present magnitude score should be interpreted as at least Medium with high confidence (it is possible it may be higher but there is considerable interannual variability and this rating is taken to be for a multi-year average). For future periods, risk magnitude is assessed as High with medium confidence regarding average multi-year yields but the role of extreme events for individual years remains more uncertain.

**Table 3.18** Magnitude score for risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind)

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium (High confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)
<b>Northern Ireland</b>	Medium (High confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)
<b>Scotland</b>	Medium (High confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)
<b>Wales</b>	Medium (High confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)	High (Medium confidence)

### 3.7.2 Extent to which current adaptation will manage the risk and opportunity (N6)

When compared to agriculture, which shows generally low levels of proactive planned adaptation, forestry has more evidence of co-ordinated adaptation planning, mainly through public sector forestry and the activities of national forestry agencies. Confidence in this part of the assessment is limited because few studies have investigated adaptation issues at management level although there is a wider body of research for the land sector, extending beyond climate change responses (e.g., uptake of soil conservation measures – see Risk N4), that generally shows a disjunct between policy aspirations and actual actions as implemented on the ground by land managers.

### 3.7.2.1 Effects of current adaptation policy and commitments on current and future risks and opportunities (N6)

#### 3.7.2.1.1 UK-wide

This topic is situated within the policy domains of Defra (England), Scottish Government Agriculture and Rural Delivery Directorate (Scotland), Welsh Government (Wales) and DAERA (Northern Ireland).

Adaptation policy remains rather general in terms of objectives and mechanisms to maintain or enhance domestic agricultural or forest production, rather than to develop and implement specific actions. However, the position is further complicated by EU-exit regarding how new international agreements will modify the current policy landscape including how production objectives will interact with regulatory requirements, support payments, and associated cross-compliance obligations that will replace EU Common Agricultural Policy (CAP) obligations. In addition to the new UK Agriculture Act 2020 which will primarily cover England, policy implementation for the other nations is also similarly in transition and will have additional interactions depending on their level of alignment with other parts of the UK in addition to divergence from the EU CAP.

As many farms are reliant on subsidy support to augment income from production, the specific details of these policy developments will be crucial for determining both the productive capacity of farmers and also the interactions with the wider environment, into which adaptation responses will also develop and evolve.

This transitional phase means that, at present, only indicative rather than detailed information on the new policy landscape, including for both incentives and regulation, is available. Therefore, it is not clear at the time of this assessment how the role of markets and policy will act to shape decisions across different types of land use and land quality. For example, a rather different outcome might be expected on lesser quality or marginal land which is generally more dependent on subsidy support (notably agri-environment schemes) compared to more market-orientated decisions on higher agricultural quality where the current focus on production may be expected to continue. In addition, there are likely to be notable differences across countries and regions of the UK in terms of both policy support and favoured land uses. This uncertainty therefore constrains assessment of climate-related risks and opportunities and adds to the future uncertainty.

However, based upon current actions, and discussions with stakeholders, it is probably fair to highlight that the current policy emphasis in our view remains focussed on enhancing 'climate resilience' in agriculture (with resilience here interpreted as improved protection for current production systems), especially via genetics and crop breeding. Genetic improvement networks have been developed to help reduce the long lead times between development and implementation, which can extend to 15-20 years. Rather less emphasis is currently placed on developing good practice for anticipatory adaptation at farm level which may require a shift to new modes of production or alternative land uses. In consequence, the National Audit Office has previously found that Defra "has not provided the necessary guidance to enable farmers to plan how to adapt their businesses or how to work collaboratively with other farmers".

More generally, across the UK, advice to land managers is provided through updates that focus on the known linkages between seasonal/annual conditions and management requirements to achieve production objectives, as exemplified by the 'Forage for Knowledge' initiative, AHDB crop development reports, and guidance from forestry advisors. At the level of government agencies, guidance and advice is also provided to land managers in terms of nature conservation, soil protection, and water resources, including compliance with policy requirements. In some cases, this has been further extended to include climate change adaptation guidance (e.g., Natural England adaptation manual). However, it is also often recognised that there is a gap between aspirations and delivery in practice, often because guidance needs further refinement to meet specific local contexts (and this aspect is usually covered through payments to specialist consultants).

As reported in previous CCRA, and for which we interpret a similar comparison pertains for CCRA3, a clearer strategy and evidence of long-term adaptation planning is evident in the forestry sector as influenced by the longer time frame for trees to reach maturity and long-term plans for woodland expansion, especially to help achieve Net Zero objectives. In addition, there has been more emphasis, as shown in national forestry strategies, of the need for forestry production to be integrated within a multifunctional landscape and to provide multiple ecosystem services (including the role of woodlands in carbon storage, flood alleviation etc.). Some forestry grants also require that future climate projections are considered when selecting species for planting, in order to comply with the UK Forestry Standard (UKFS). A UKFS Practice Guide on adaptation is expected to be published during 2021 to help forest managers/owners meet the adaptation requirements of the UKFS. However, there is still limited information on how much of this adaptation guidance is actually being implemented, especially in the private forestry sector where evidence suggests adaptation actions have been more limited (e.g., Lawrence and Marzano, 2014). Climate change mitigation (often linked with carbon offsetting) often appears a stronger driver in land management objectives, although surveys do identify that adaptation is a priority issue for land managers (e.g., British Woodland Survey 2015 and 2020 – see Hemery *et al.*, 2020). However, surveys also identify that a significant proportion of woodlands remain 'unmanaged' and are not considered to be fulfilling their full potential (e.g., Royal Forestry Society, 2019).

Increasing awareness of wildfire risk is also reflected in policy developments, although this is currently more evident in the forestry sector than for agriculture. These developments include increased use of knowledge exchange to develop shared awareness of changes in risk and through ongoing developments for best practice in fire risk reduction, as represented by regional wildfire networks and national wildfire fora for England, Scotland and Wales. Nevertheless, there is also a concern that the level of awareness and engagement is variable (Gazzard *et al.*, 2016), possibly related to the level of recent experience with the hazard; this is reflected in the extent to which climate change adaptation is included in strategic plans, which for some locations is extremely limited (see also Box 3.1: Introduction).

Planning policy for land use is based upon protection of best quality land (BMV or PAL), although implementation of this varies across the UK with a higher sequential test to justify the use of this land for other purposes in Scotland and Wales compared to England. As identified in CCRA2, future projections of changes in land capability to 2050 and beyond are now available for most of the UK (excepting Northern Ireland) to provide a basis for forward planning, including recent developments in Wales through the Climate Suitability and Capability Programme (CSCP) initiative to provide

predictive agricultural land classification maps based upon UKCP18 for planning authorities. However, challenges remain in communicating this information to planners, including how to represent the reality that climate change can have multiple future pathways rather than to over-rely on one 'predictive' map in strategic planning. Use of forward projections in land use planning documents therefore remains very limited.

Regarding implications of risks to agricultural production affecting domestic food supply, Clause 17 of the new UK Agriculture Act 2020 sets out a duty for the UK government to report on food security to Parliament at least once every 5 years. In addition to domestic supply, reporting will cover a range of current issues relevant to food security including global food availability; supply sources for food, the resilience of the supply chain for food; household expenditure on food; food safety and consumer confidence in food (see Chapter 5: Kovats and Brisley, 2021; and Chapter 7: Challinor and Benton, 2021 for further details of these issues).

Another notable issue regarding negative 'externalities' arising from agriculture is that multiple schemes are available to the land manager, with some obligatory regulatory requirements and others as voluntary opt-ins. However, our assessment of the current position is that they are not often joined up to maximise their co-benefits, including for climate change adaptation. For example, the Catchment Sensitive Farming (CSF) initiative is an important development for addressing diffuse water pollution from agriculture in priority catchments (as required by Water Framework Directive targets and drinking water quality standards) but a catchment-sensitive approach is also required to better manage flood risk and low water flows, often in the same priority catchments. Without further policy development, this could lead to inadvertent adaptation trade-offs rather than synergies. However, it should also be noted that multi-stakeholder partnerships have become established in some catchments and are providing a more integrated approach to land/water interactions based upon local or regional contexts throughout the UK (e.g. 'Upstream Thinking' project in SW England; Tweed Forum in the Scottish Borders/Northumberland etc.).

#### 3.7.2.1.1.1 Flood risk management

The CCRA3 Floods Study (Sayers *et al.*, 2020) provided some indicative evidence on the level of additional protection that a continuation of current adaptation will provide for reduced flood risk on land that is currently identified as being of higher quality (BMV or PAL)(Table3.19). By comparison with the no adaptation results it can be seen that coastal flood risk would be significantly reduced for England and to a lesser extent for Wales (little change for Scotland and Northern Ireland), whereas for fluvial flooding it was found that there would not be much change in the area of land at risk.

The increased risk to agricultural land from flooding also is intended to be included in post-CAP plans for each administration, including a greater role for NFM in addition to protection for better quality farmland, although implementation details are still in development. It is therefore not yet clear whether current cost-benefit formulas used in options appraisal for flood and coastal erosion protection will be further refined to include the strategic value of the best quality farmland.

**Table 3.19.** Changes in land at significant risk of flooding (frequency of 1 in 75 year or greater) with continuation of current adaptation policies (i) coastal (ii) fluvial. Source: Sayers et al. (2020)

### 3.7.2.1.2 England

The UK Agricultural Act 2020 represents one of the most significant pieces of legislation for farmers in England for several decades. The Act sets out provisions for transition between 2021-2028 away from the former CAP subsidy scheme, replacing direct payments based on land area in agricultural production with a scheme providing payments for 'public goods'.

Agri-environment and single farm payments (and any other related grants) are, therefore, in transition to a new Environmental Land Management scheme (ELM - see Risk N1 for further details) from 2024, also including productivity grants (e.g., for new technology). As components of ELM, the Sustainable Farming Incentive will be aimed at facilitating land management in an environmentally sustainable way, Local Nature Recovery will aim to deliver local environmental priorities and Landscape Recovery will aim to deliver landscape and ecosystem recovery through long-term land use change projects.

This new approach will also remove an obligation to farm the land that existed under the EU CAP, potentially therefore facilitating greater integration with forestry and agro-forestry uses. Current cross-compliance arrangements are, therefore, being phased out and will be replaced by new requirements, including plans for an improved inspection and enforcement process, and common regulations for animal welfare. Current plans also indicate that support packages may also aim to add additional incentives that support important local or landscape-scale benefits, which could help address the wide diversity of different contexts for land management. However, specific consideration of how ELM payments and the other schemes will support adaptation to climate change is missing at the time of this assessment.

The Forestry Commission (2020) has produced adaptation guidance for woodland management ('Managing England's woodlands in a Climate Emergency') that includes diversification of species, genetics, and stand structure. This guidance suggests that where timber production is a high priority in the woodland management objectives, or the planting is not adjacent to a site recognised for its local genetic integrity, that an assisted migration approach is considered, also contingent on an owner's attitudes to risk. Assisted migration strategies are suggested based upon provenances from 2 degrees latitude south of the planting site, as these generally outperform the local provenance and this is considered a safe distance over which to transfer material, or from a more forward-looking (but potentially riskier) perspective upon provenances from up to 5 degrees latitude south that match climate change projections out to 2050.

A new FCERM government statement and strategy includes farmland within its generic framework of 'resilient people and places' and aims to go further than most existing policies by considering resilience in the context of different future climate change scenarios through adaptive pathways.

#### 3.7.2.1.3 Northern Ireland

In Northern Ireland, the 2014 'Going for Growth' strategy, which aims to enhance production capacity, has recently been complemented by a Sustainable Agricultural Land Management Strategy developed by an Expert Working Group (2020). Although the latter only contains rather limited reference to the need for adaptation in the context of improved 'resilience against extreme events', it is notable for proposing a progressive roadmap that recognises the synergies between production gains and improved environmental outcomes. In particular, it highlights current issues with poor soil quality and sub-optimal grass utilisation, together with a significant proportion of land with insecure tenure, and proposes making soil health a central focus of the strategy complemented by considerable improvements in soil/water monitoring (including use of GPS and LiDAR technology) and land manager engagement in policy development. Based upon these developments, it is proposed that production capacity could be enhanced so that in terms of grass utilisation this would achieve at least one extra tonne of dry matter per hectare and with improvements in grass and silage quality of 5 to 8%.

#### 3.7.2.1.4 Scotland

In Scotland, the SCCAP2 highlights knowledge exchange schemes, such as Farming for a Better Climate and Monitor Farm Scotland, which aim to take a whole farm approach to improve both productivity and sustainability, although much of the emphasis to-date has been on reduction of farmland GHG emissions. Scotland's Forestry Strategy presents a 50-year vision based upon

principles of sustainable forest management and a 10-year framework for action, including commitments to increase woodland cover to 21% of total land area by 2032, with the 2020-21 12,000ha/yr woodland expansion target being incrementally increased each year to deliver 18,000ha/yr for 2024-25. SCCAP2 also reaffirms the importance of further development of the national Land Use Strategy for adaptation planning, especially for the uplands, although many of the future challenges also require equal attention for the lowlands and upland-lowland interactions (and rural-urban interactions). This latter issue is especially notable because SCCAP2 and the Land Use Strategy both advocate an ecosystem services framework and recognise challenges in correcting imbalances between agricultural productivity and other ecosystem services, together with the need for integrated planning across multiple land uses to ensure a sustainable flow of services. The Land Use Strategy for 2021-2026 has recently been launched and a development plan is expected to follow later in 2021. Work is also in progress to update the Land Capability for Agriculture classification system based upon climate change data from UKCP18 to provide a basis for forward-based land use planning.

#### 3.7.2.1.5 Wales

The Welsh Government has published 'Sustainable Farming and our Land' with initial plans for post-EU-exit arrangements. This includes proposed objectives to ensure ecosystem resilience consistent with the duty set out in the Environment (Wales) Act 2016, although explicit details for climate change adaptation actions remain to be developed. A national forest strategy 'Woodland for Wales' was released in 2018 recognising the importance of woodlands and including a new short-term target to increase woodland cover by at least 2000ha/yr from 2020 to 2030 and beyond, although in previous years very little new woodland has been created. In 2019, the second Welsh National Adaptation Programme 'Prosperity for All: Climate Conscious Wales' identified plans to integrate adaptation into the Sustainable Farming Scheme for Wales via evidence reviews, research, working group proposals and a Sustainable Brand Values Scheme, together with ongoing work to implement new land capability maps and other information from the Capability, Suitability and Climate Programme (as referred to above) as a basis for strategic land use planning. In addition, Farming Connect provides knowledge exchange, innovation and advisory services for farming and forestry businesses in Wales and evidence gathering to implement climate-smart actions in the red meat and dairy sector are being supported through Aberystwyth University. Guidance has been produced by Natural Resources Wales (Natural Resources Wales, 2017) looking at forest diversification of species, genetics, and stand structure.

Welsh Government published its new FCERM national strategy in October 2020. In the strategy, the Welsh Government commits to working with partners to encourage appropriate land management practices and NFM schemes to reduce run-off and soil erosion.

#### 3.7.2.2 Effects of non-Government adaptation (N6)

As referred to above, short-term reactive responses at farm level still tend to dominate in agriculture, whereas the longer planning horizons in forestry appear to have encouraged more longer-term planning, at least in the public sector. Some adaptation measures have long lead times, including development of climate-resilient cultivars or livestock genetic programmes, and measures to adapt to water availability constraints in drier areas. For agriculture, an important yield gap (and hence production gap) remains between what is technically feasible and the actual product that is

delivered (Schils *et al.*, 2018; Senepati and Semenov, 2019). In terms of the development of new cultivars, there are inherent challenges in incorporating multiple climate risk factors into genotypes and ideotypes because gene selection to reduce one type of risk may exacerbate another risk. Research suggests that for years with favourable weather, optimal adaptation (notably improved N-use efficiency) on some farms could lead to wheat yields reaching 20t/ha (Mitchell and Sheehy, 2018), although there are significant barriers to achieving this in the wider sector (see below).

Unfortunately, practitioner surveys remain irregular, making it difficult to draw firm conclusions on trends relating to adaptation in agriculture. However, the information available (Defra and AHDB surveys etc.) suggests that although some forms of adaptation may be increasing, such as those related to water resources and flooding, this is often triggered as a response to specific events, and in general that adaptation remains rather patchy and sporadic rather than as a component of a longer-term strategy.

Defra Farm Business Surveys show that the percentage of farm businesses using different water sources has stayed relatively similar (up to 2015-16), with some further details also available from AHDB surveys (ADAS, 2019). An AHDB survey of farmers indicated that most irrigation water continues to be sourced from groundwater (ca. 30 million m<sup>3</sup>) compared to surface water (ca. 15 million m<sup>3</sup>) with very little provided by alternative supplies such as harvested rainwater. The same AHDB survey showed that about 67% of respondents had some form of water storage (reservoir, tank or rainwater harvesting) and about 65% use specialist irrigation scheduling software, with soil/substrate moisture monitoring, timing systems, or humidity/evapotranspiration sensors also frequently used. The mostly commonly used water efficiency measures were night irrigation, improved monitoring and scheduling of crop water use, installing new irrigation technologies/systems, and prioritising irrigation of different crops. Lesser used actions included trading water with other users, adjusted abstraction periods/extended licences, installing rainwater harvesting/recycling, and applying voluntary restrictions during shortages. Currently, about 35% of the volume of water licensed for spray irrigation is identified as drawn from winter storage and this proportion is steadily increasing.

Similarly, in livestock farming, the available evidence suggests that most responses are mainly reactive and short-term adjustments rather than long-term decisions. For example, analysis following the 2018 drought in England found that responses were mainly focussed on coping strategies to address feeding shortages with much less emphasis on changes in land use or farm management to enhance fodder resilience against future droughts (Salmoral *et al.*, 2020).

In forestry, the British Woodland Survey 2020 (BWS2020: Hemery *et al.*, 2020) identified a high proportion of respondents were strongly motivated to diversify tree species for biodiversity (median value 9 out of 10), ecosystem services (median value 7/10), or carbon (median value 5/10), but that, for those owners with available land, lack of grant aid or the complexity of the grant/regulatory scheme acted against expansion of woodland cover. Previous surveys have also indicated that production goals are typically the main reason acting against species diversification. Stakeholder perceptions are obviously strongly influenced by personal experience and a preference for those species that are assumed to be more productive based upon past performance may neglect new factors (e.g., pests and pathogens for forestry – Risk N8) that could imply a stronger case for

diversification. Knowledge exchange and outreach associated with new species trials and demonstration plots or stands can therefore have a valuable role in updating risk perceptions. BWS2020 found that most respondent woodland owners (69%) did not have a UKFS compliant management plan in place. Whilst concerns have been expressed about the sector and geographic representativeness of the BWS, the lack of other comprehensive surveys means that it continues to be an important source for adaptation progress. Evidence from specific locations in the UK suggests adaptation remains limited in the private sector (Lawrence and Marzano, 2014).

Practitioner networks provide an important route for knowledge exchange both in agriculture and forestry, and in some cases linked with accreditation schemes to provide quality assurance (e.g., LEAF). In addition, the Nature Friendly Farming Network (NFFN) is an example of farmer-led movement interested in improved climate change responses, although its current emphasis has been on reducing GHG emissions.

### 3.7.2.3 Barriers preventing adaptation (N6)

Several recent reports have identified barriers to proactive actions in the land sector which include: path dependency and inertia in land use decision-making (many reasons, often cultural); previous confusion on target outcomes between different policy initiatives; challenges related to insecure land tenure; mismatch between grant incentives, markets, and the longer-term requirements of both climate change adaptation and mitigation (eg. RSA, 2020; CCC 2018b). In addition, there are well-known cultural differences between agriculture and forestry meaning that these land uses are not usually considered together, resulting in a fragmented approach to land use decisions, and often that forestry is pushed to the more marginal land (e.g., Brown, 2020). In addition, limited use of near-term climate forecasts (seasonal to decadal) as well as longer-term climate projections continues to be a feature of agricultural decision-making and crop breeding (Falloon *et al.*, 2014; Falloon *et al.*, 2015), although there has been greater uptake within forestry.

Despite potential multiple benefits (including for reduced soil erosion and nutrient runoff, shelter for livestock, and carbon storage), agroforestry remains very underdeveloped as a land use option in the UK with only 3.25% (549,600 ha) of total agricultural land under agroforestry use, almost all of it in silvo-pastoral systems (den Herder *et al.*, 2017). Only ca. 2,000 ha of land is in silvo-arable use, mainly in England and Wales. The reason for this appears to be primarily related to the assumed loss of productivity by farmers.

In agriculture, government has usually acted to provide grants to farmers to cover losses from extreme events. Insurance cover is available in the private market, but often limited due to the potential for catastrophic losses, and the problems of adverse selection and moral hazard, and uptake remains limited especially amongst smaller farmers. Full multi-hazard crop insurance across the sector is generally only considered viable with government backing, with the private sector as administrator, but this may also be due to the considerable inertia in the sector previously noted.

Investment in new infrastructure or machinery to improve production efficiency or environmental outcomes can also be a barrier. Many irrigated holdings are constrained by the capacity of their

irrigation infrastructure meaning they have an effective design limit equivalent to an evapotranspiration rate of 2.5 mm/day on average (Gadankis *et al.*, 2015), yet this can be exceeded during current drought periods (e.g., summer 2018) and expected to be considerably exceeded by the increase in future evapotranspiration rates in future (ca. 4-5 mm/day by the 2050s under a central UKCP18 projection). This limitation may be alleviated by increased use of on-farm storage to take advantage of increased winter rainfall, but again this requires further investment and capital costs can be significant.

In forestry, information from the British Woodland Survey 2020 and previous surveys suggests that awareness of the range of impacts from climate change is increasing. However, planned adaptation actions to reduce risks remains limited (Hemery *et al.*, 2020), and stakeholder interviews suggest that future uncertainty, including as communicated through climate projections, remains a significant barrier (Lawrence and Marzano, 2014)

As highlighted in the chapter Introduction (Box 3.1), management of wildfire risks, although evolving, is sometimes fragmented amongst multiple organisations and strategies are yet to fully incorporate climate change (Gazzard *et al.*, 2016).

#### 3.7.2.4 Adaptation shortfall (N6)

Despite recent policy developments, there is no clear evidence that climate risks or opportunities are being successfully managed, nor is there yet a dedicated plan or strategy in place to support this process for any of the UK nations. Strategic planning is more in evidence for the forestry sector compared to agriculture, but much of the impetus of this is provided by climate change mitigation (especially Net Zero) rather than climate change adaptation, although adaptation guidance is now being enhanced. As identified above, the presence of significant barriers in the land sector means that there is a known disjunct between policy aspiration and the reality on the ground, and our assessment identifies that this remains as a major problem.

A further significant challenge is that there is as yet no long-term integrated policy for changes in strategic land allocation that integrates agricultural and forestry production together with other land use objectives in the context of climate change (adaptation and mitigation). For example, the recent RSA (2020) report on the future of the land identified a strong need for a more coherent land use strategy for the UK, and the Food, Farming and Countryside Commission (2021) have recommended a place-based national land use framework for England. Although Scotland has pioneered an integrated approach through the Land Use Strategy, this has not yet been translated into spatial planning guidelines and targeted measures that both maintain production capability and deliver other land use objectives in the context of climate change. Similarly, in Northern Ireland, the proposed Sustainable Land Management Strategy (Expert Working Group, 2020) provides a thorough diagnosis of existing problems and a vision for a more sustainable future, but as yet is only at the visioning stage and has not been translated into actions on the ground. In Wales, an enhanced evidence base is being provided through the CSCP research initiative and the next stages will involve this being translated into policy implementation guidance documents.

We therefore assess there to be a significant adaptation shortfall for England, Scotland, Wales and Northern Ireland regarding management of this risk and opportunity. This assessment has only low confidence because evidence on adaptation outcomes remains very limited although the patchy evidence for adaptation taking place on the ground should be cause for concern in itself, especially for agriculture. Whilst there are developments in national policies that have the potential to significantly address the gap, these remain in progress and current action is not sufficient to manage the future levels of risks down to low magnitude levels. This should be of especial concern because of policy aspirations to increase the proportion of domestic production as compared to international sources.

### 3.7.2.5 Adaptation Scores (N6)

<b>Table 3.20</b> Adaptation scores for risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind)			
<b>Are the risks and opportunities going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Very Partially* (Low confidence)	No (Low confidence)	Very Partially* (Low confidence)	Very Partially* (Low confidence)

\* Primarily for forestry production in the public sector, although goals are more multifunctional

### 3.7.3 Benefits of further adaptation action in the next five years (N6)

Different types of benefits from further actions are summarised below:

#### 3.7.3.1 Skills, training and knowledge (N6)

CCC (2020) identified that government should develop an effective strategy to address the historical productivity gap in UK agriculture including: skills, training and knowledge exchange; rural infrastructure and connectivity; and delivering R&D at farm level. The shortfall identified in this CCRA report provides further support for such a development. A major impetus for this strategy should be to better link adaptation and mitigation across the land use sector as a whole including combined pathway(s) to achieve the 2045/2050 Net Zero outcome whilst also delivering on sustainable production and environmental quality goals. There should also be considerable benefits from extending such a strategy across the land use sector as a whole, and especially in integrating developments in both agriculture and forestry together more effectively, both for production and wider environmental goals.

#### 3.7.3.2 Managing synergies and trade-offs between climate change mitigation and adaptation (N6)

From an adaptation perspective, managing risk and uncertainty suggests the need for increased diversity in cropping systems and across different land uses which may conflict with the assumed land optimisation agenda for Net Zero. However, there are also considerable synergies that can be delivered in improved use and management of land to deliver combined production and Net Zero

goals whilst also aiming to avoid negative externalities (e.g., low carbon farming; improved N-use efficiency; enhanced soil quality measures; water resources and flood management). A notable example would be schemes to increase uptake of N-fixing crops and forages, both in arable crop rotations and in permanent pastures, as supported by knowledge exchange and guidance on the combined adaptation/mitigation benefits. Another example would be increased adoption of schemes to improve soil quality, including use of no-till farming to enhance soil carbon and provide benefits (Cooper *et al.*, 2021), and measures to avoid soil compaction (Chamen *et al.*, 2015), both of which have been shown to have co-benefits for maintaining yields and productivity over the longer term.

The CCC (2020) Net Zero pathways identify the need to sustainably increase crop productivity and livestock grazing intensity in order to make additional space for woodland expansion and bioenergy crops on former agricultural land. The challenge is therefore how to achieve this in a changing climate on suitable land that does not introduce additional risks. For example, the CCC (2020) Net Zero balanced scenario assumes that average planting rates of miscanthus, short rotation coppice and short rotation forestry scale up to 23,000 hectares per year from the mid-2020s. Currently perennial energy crops made up just 0.2% of UK arable areas, while short rotation forestry (SRF) for bioenergy is virtually non-existent. This therefore implies major land use change over a few years and at a scale not previously seen in Britain on this timescale, and to meet sustainability criteria will require investment in a much stronger evidence base to ensure that it is consistent with the changing climate risks described in this CCRA.

An alternative approach to reach Net Zero has been outlined by the Food, Farming and Countryside Commission (2021) based upon agroecological principles and a return to mixed farming systems (cropping, livestock and agroforestry) throughout the UK. It would also involve re-establishment of more arable in the western UK regions and more pasture in the east. This strategic vision also remains largely untested from a climate change adaptation perspective, notably the implications from expected lower and less volatile annual crop yields and putative advantages for biodiversity, soil and water quality, and landscape character etc. Important insights may therefore be obtained by contrasting this approach with the CCC (2020) Net Zero pathways, especially across scales, regarding transition to an integrated spatial strategy to maximise delivery of Net Zero together with adaptation outcomes.

The role of policy reform, including current developments such as ELM and equivalents in the DAs, will be crucial in maximising such synergies, especially with Net Zero objectives. This should therefore seek to avert the negative distorting effects that have occurred previously when goals have been defined in isolation without consideration of side-effects or local contexts. For example, the provision for local-scale and landscape-scale schemes in ELM can provide this framework, although presently details for their implementation remain to be established. In this context, a key component of policy reform will therefore be suitable indicators that provide a more holistic measure of desired land management outcomes as related to long-term sustainability.

### 3.7.3.3 Integrated soil and water management (N6)

A range of potential mechanisms have been identified that may allow adaptation of irrigation-fed farming (Rey *et al.*, 2017), either to better manage demand through improved irrigation efficiency or

prioritising high value crops, or to enhance supply such as by increased use of water storage. For example, a survey of 66 horticultural farms in England found that on average, water requirements could be reduced by 35% to achieve the same output (gross margin) (Gadankis *et al.*, 2015). In addition, reform of regulatory arrangements such as water sharing and water trading with reallocation of unused licenses, can have beneficial outcomes, as has been further developed in other countries.

Furthermore, additional adaptation responses for addressing agricultural drought can include:

- shifting to earlier planting to avoid coincidence of high drought risk with most sensitive growth stages.
- selecting more drought tolerant crops and varieties, including those with deeper rooting characteristics or other advantageous traits.
- enhanced soil management responses to enhance water retention such as reduced or no-tillage systems, or organic amendments, and enhanced infiltration.

There are likely to be considerable benefits from further trialling and implementation of such responses in drought-sensitive areas, including further refinement to match with local land use contexts.

For forestry, as discussed in further detail with regard to pests and pathogens in Risk N8, but equally applicable to drought risk, there may be important advantages from further consideration of schemes to enhance genetic adaptability of key species, in addition to species diversification (Whittet *et al.*, 2019). This could include increased use of drought-resistant varieties (e.g., from warmer, more southerly locations) in the provenance of seed stock.

Improved awareness and understanding of adaptation options, which in the present situation and especially for agriculture shows a strong path dependency effect based upon continuation of past decisions, could be enhanced through improved availability and communication of monitoring (especially taking advantage of latest developments in remote sensing). This is especially applicable to soil moisture monitoring as the key variable linking drought and wetness risk to plant growth, together with further research to develop indices and indicators that can communicate changing risk levels to land managers in a practical context (Haro-Monteagudo *et al.*, 2018; Parsons *et al.*, 2019).

#### 3.7.3.4 Flood risk management (N6)

The benefits of additional action over and above what is planned is shown by the Enhanced Adaptation option investigated by Sayers *et al.* (2020) which investigated further adaptation for flood risk management in the context of increased implementation of managed coastal realignment (MCR) and natural flood management (NFM). Managed realignment is one of four options available to coastal local authorities through Shoreline Management Plans (SMPs) to manage local circumstances (see Risk N17).

As shown by Table 3.21, and by comparison against a continuation of existing adaptation (Table 3.19 above), it can be seen that although there is a small additional reduction in flood risk for some locations there are also anomalies where there is an increased area of existing high-quality land at risk which is due to the assumed implementation of MCR/NFM. This analysis is therefore beginning to highlight the complex adaptation trade-offs that will occur from loss of existing farmland and its production value when compared against the other benefits that may be gained from its strategic use to manage flood risk. In either case, it would generally be assumed that the most productive land (i.e., BMV or PAL) would be protected as a strategic resource unless prohibitively expensive to maintain an appropriate level of flood protection (which may include increased use of lesser quality of land elsewhere in the catchment or coastal zone as the flood alleviation zone).

**Table 3.21.** Changes in land at significant risk of flooding (frequency of 1 in 75 year or greater) due to an extended ambition for adaptation policies (i) coastal (ii) fluvial. Source: Sayers et al., (2020)

i) Coastal					
Assets at significant risk	Baseline (Ha)	2050s on a pathway to +2°C in 2100	2080s on a pathway to +2°C in 2100	2050s on a pathway to +4°C in 2100	2080s on a pathway to +4°C in 2100
BMV land England	68,796	57%	74%	73%	97%
PAL Scotland	11,082	5%	8%	9%	14%
BMV land Wales	10,726	21%	38%	37%	66%
BMV land N. Ireland	65	0%	0%	0%	0%
ii) Fluvial					
Assets at significant risk	Baseline (Ha)	2050s on a pathway to +2°C in 2100	2080s on a pathway to +2°C in 2100	2050s on a pathway to +4°C in 2100	2080s on a pathway to +4°C in 2100
BMV land England	259,248	22%	17%	23%	23%
PAL Scotland	90,727	26%	32%	38%	49%
BMV land Wales	52,413	47%	45%	58%	69%
BMV land N. Ireland	3,442	11%	30%	50%	68%

Partnership funding schemes now aim to take loss of agricultural production into their calculations. In England, the new government flood and coastal erosion risk management policy statement and associated National Flood and Coastal Erosion Management Strategy, both published in 2020

represent an enhanced adaptation commitment. Analysis has not yet indicated how the level of risk management compare with the Enhanced Adaptation option in the Sayers et al. (2020) study which used a different set of assumptions than those set out in the new policy statement and management strategy for England.

#### 3.7.3.5 Encouraging innovation and diversification (N6)

As recognised in section 3.7.2.5, there are also underlying socioeconomic barriers to be addressed in order to facilitate a more proactive and integrated approach to adaptation decision making amongst land managers, including security of land tenure, access to new technology, and divergent cultures between agriculture and forestry interests. This may require new approaches to risk sharing and further schemes to encourage innovation, including new enterprises and entrants. In addition, the identified challenges for production identify an increased need to establish more resilient supply chains, and especially to maximise enhanced opportunities for local food production including potentially new or novel crops for specific locations (see also Risk N9).

Analysis in forestry has shown the type of management strategy can have a strong influence on the future provision of forest ecosystem goods and services (timber production, standing biomass, and biodiversity index: Ray *et al.*, 2019). This analysis investigated alternative diversification and prioritisation strategies to business as usual, including different species and silviculture systems (increased short-rotation forestry or continuous cover forestry etc.) based upon relationship to a single climate projection from the HadRM3 climate model ensemble that was assumed equivalent to the RCP4.5 scenario. Dothistroma needle blight could reduce standing biomass (by up to 3 t/ha) and timber volume (by up to 5 m<sup>3</sup>/ha) dependent on management system. Diversifications, as represented notably by a broadleaved species management priority or other ‘selected species’ priority, were shown to improve standing biomass and biodiversity, but slightly reduce timber volume in all scenarios. In some key locations, such as North Highland and Moray & Aberdeen, changes in species selection and silvicultural management could improve biomass provision, timber production, and biodiversity whilst reducing Dothistroma risk, potentially providing a win-win outcome.

A key challenge, especially for agriculture and horticulture, is that climate change inevitably will involve increased unpredictability of risk, even with ongoing improvements in forecasting systems. However, although farm and land use diversification provide a means to accommodate this unpredictability, this potentially has a trade-off with economic performance and is counter to trends towards farm specialisation over recent decades. Diversification would therefore require policy support, including options based upon grants, tax breaks, legislative enablers, and mechanisms for collective action, in order to enhance adaptive capacity for this trajectory.

#### 3.7.3.6 Research (N6)

There are also important evidence gaps for this risk topic and addressing these would also improve targeting of adaptation measures based upon key climate sensitivities. These knowledge gaps remain especially notable for grassland and livestock systems where, despite recent improvements, evidence is still somewhat limited regarding linkages between impacts and adaptation responses

across the wide diversity of livestock systems that occur throughout the UK. General reviews of evidence (e.g. Rojas-Downing *et al.*, 2017; Wreford and Topp, 2020) have highlighted a range of adaptation options, included improved grazing management (timing, plant species etc.), genetic improvements, nutritional and diet management, infrastructure changes, and enhanced responses to pests and pathogens (see also Risk N7), but these need further refinement in the UK context and also to take better account of concurrent activities to improve the efficiency of livestock production to meet Net Zero targets.

In addition, although ‘sustainable intensification’ is an important focus of current research agendas, there is presently limited inclusion of adaptation in these programmes. In this context, evidence suggesting that landscape configuration, especially inclusion of semi-natural habitats together with farmland, has benefits for yield stability (Pywell *et al.*, 2015; Redhead *et al.*, 2021), deserves further detailed investigation in a range of different contexts as a prospective key adaptation strategy.

#### 3.7.3.7 Coordination (N6)

As identified above, risks and opportunities for agricultural and forestry productivity have important interactions with other CCRA chapters and show the potentially pivotal importance of this issue for rural communities. This identifies the need for better coordinated actions between government and the land use sector in terms of both enhanced productivity but also protection of natural resources (water, soil, biodiversity, land etc.) on which productivity depends. In terms of adaptation planning, there are critical decisions to be made on the long-term sustainability of some types and modes of production in their current locations, and in some cases whether investment should be moved towards new areas that are likely to be more climate resilient in the longer term (especially on the context of water availability). This challenge emphasises the importance of also recognising that agriculture and forestry enterprises are businesses and that adaptation is also strongly dependent on key adaptation issues in a business context, such as access to capital (including government grants or subsidies), availability of new skills and knowledge, networking and business security (this will also involve further developments in associated initiatives, such as insurance (see Chapter 6: Surminski, 2021).

#### 3.7.3.8 Indicative costs and benefits of additional adaptation (N6)

There are a number of studies on costs and benefits of adaptation actions (Watkiss and Hunt, 2018), although their conclusions depend on the modelling approach (i.e., whether using farm level analysis, crop models, econometric analysis, or partial or general equilibrium models). Early studies using crop productivity models tend to identify increased use of irrigation and fertiliser to address changing yields, but rarely covered potential limits (e.g., water availability or implications of fertiliser use). Another series of models use partial or general equilibrium models to analysis adaptation options including trade, shifting crop types and land-use expansion. These highlight important issues of market driven adaptation, and that changes that occur from impacts in the UK need to be seen in the European and even global context. Such studies (e.g., Hristov *et al.*, 2020) report that large negative climate change impacts on productivity outside of the EU can lead to large market spill-over effects which could push up production in Northern Europe (including the UK, and assuming

production capacity is available) as higher demand for some agricultural commodities outside of EU results in higher producer prices.

At local level, economic studies have found a large number of no- and low-regret options including agronomic options such as changing sowing dates, planting new cultivars or varieties, or changing management practices (Watkiss and Hunt, 2018). These are often already implemented as reactive or even planned measures by farmers as adjustments to weather and climate variability, however effectiveness is usually highly variable depending on the context for the measure and differs for crops and regions. As discussed in previous CCRA, more strategic options that have good benefit to cost ratios include increasing water supply through on-farm storage reservoirs and incentivising efficient water management, the introduction and increasing expenditures on research and development (Wreford and Renwick, 2012; Moran *et al.*, 2013; Frontier Economics, 2013). In addition, studies also support early options that focus on enhancing adaptive capacity through research, awareness, information provision, best practice and addressing barriers. This may be complemented by further investment in weather and climate services (seasonal forecasting etc.) to improve the quality of information on climate sensitivity and further support for technological developments, notably precision agriculture.

In particular, and highlighting the risks transferred from the land use sector to biodiversity, soils and water (see Risks N1, N4, N11), there is enhanced policy interest in 'climate-smart' initiatives, although here additional policy support will likely be crucial, as through agri-environment scheme payments. For agriculture, direct benefits from improved environmental protection for farm incomes (rather than society as a whole) generally take longer to accrue and include non-market and off-site benefits. For individual practices, benefit to cost ratios are often highly site-specific, with varied evidence on practices as viable standalone adaptation strategies (e.g., Kuhlman *et al.*, 2010). Previous qualitative economic appraisal by Frontier Economics (2013) found UK farming uptake of soil protection measures was relatively low, partly influenced by awareness but also financial return.

A report commissioned by the CCC from AECOM (2018) examined how taking a long-term approach to considering the risks from climate change, and anticipating land-use changes to manage these risks, could deliver net benefits in terms of the maintenance of natural capital and the services it provides. An 'adaptation pathways' approach was used to develop understanding of how the need for planned transformational change can be understood and analysed. Four case study locations were scoped for the research all of which had agriculture as a significant proportion of existing land use: Norfolk and Suffolk Broads; Somerset; the Petteril; and Moor House and Upper Teesdale. The case studies showed that in scenarios where future climate change presents a threat to current land uses, the use of adaptation pathways that consider land-use change in advance of the climate hazard event occurring deliver higher net benefits compared to waiting until the hazard has occurred. Assuming anticipatory action was taken, it was shown to hypothetically improve total net benefits over and above a business-as-usual scenario by between £2,500 per ha and £8,400 per ha across the four English case study locations analysed in report.

Posthumus *et al.* (2015), using an ecosystem services valuation approach, found that for soil erosion, use of tramline management, mulching, buffer strips, high-density planting and sediment traps were the most cost-effective control measures, with contour ploughing also cost-effective in some circumstances. However, as above, the study also found that assessments of effectiveness really

need to be made at farm level or field level, because of the wide variation in biophysical and land use contexts, emphasising again the key role of outreach and guidance in stimulating proactive adaptation actions on the ground. SRUC (2013) for the CCC also looked at soil management, considering six adaptations on a number of different crops. Under these assumptions, all the adaptations analysed (with one exception, for cover crops) generated positive NPVs. These did not require long lead times and had positive ancillary benefits, but the study still identified the challenge would be to encourage farmers to adopt them. All of this suggests that while sustainable soil management approaches have potential for reducing climate impacts, their uptake requires these barriers to be addressed, and may need a combination of awareness and incentives to realise (Watkiss *et al.*, 2019) though there are obvious opportunities to provide additional incentives through revision of the current farm payment schemes.

Livestock adaptation options have been evaluated by Dittrich *et al.* (2017). The costs involved in adapting the farming system range from simple low- or no-cost to those requiring large investments of capital and labour (Wreford *et al.*, 2015; Wreford and Topp, 2020). The lead-time and lifetime of that adaptation measure influence the choice of economic appraisal method used for the evaluation (Dittrich *et al.*, 2017). In the case of short-term decisions that require a small investment or a reversible action, cost-benefit analysis (CBA) is appropriate. On the other hand, projects that have a longer lead-time or long lifetimes require methods that incorporate uncertainty (Dittrich *et al.*, 2017). Thus, when farmers consider changing the composition of the dairy herd to maximise productivity and minimise stress, portfolio analysis, which evaluates several options in terms of herd structure, is appropriate. However, when the impact on the farmer relates to the frequency of extreme events, real option appraisal can be used as it allows for learning over time, and this method may be more suited to natural flood risk management measures to protect livestock and agricultural land, and housing to protect animals from heat.

Studies on adaptation costs and benefits in relation to sustainable forestry management investigate the challenges in making long-term decisions over individual or multiple rotation cycles. Increasingly these show the advantages from moving to a more diversified system rather than monocultures as developed in the past, as also consistent also with the general shift towards multifunctional forestry, including the increasing present and future threats from pests, pathogens and INNS (Risk N8) (e.g., Ray *et al.*, 2019).

### 3.7.3.9. Overall urgency scores (N6)

**Table 3.22** Urgency scores for risks to and opportunities for agricultural and forestry productivity from extreme events and changing climatic conditions (including temperature change, water scarcity, wildfire, flooding, coastal erosion, wind)

Country	England	Northern Ireland	Scotland	Wales
Urgency score	More action needed	More action needed	More action needed	More action needed
Confidence	Medium	Medium	Medium	Medium

Given the potentially high levels of future risk across the UK, together with a significant gap in adaptation sufficient to manage this risk down to a low level by 2100, particularly for agriculture, 'more action needed' urgency scores have been assigned to England, Wales, Scotland and Northern Ireland. The urgency is further underscored by the usual long lead times between policy initiatives and effective action on the ground for the land use sector, including challenges in overcoming decision inertia and high potential for lock-in to an unsustainable future.

More action is especially required to match land uses with the best use of the land in terms of capability to provide different functions and services, notably productive capacity in the context of this specific risk, but also recognising the importance of other land use functions and ecosystem services (soil quality, water quality, flood risk alleviation, carbon storage etc.). This will require a more integrated approach to strategic land-use planning bringing together both climate change adaptation and mitigation. In addition, as described above, addressing threats to productivity requires a supporting policy framework to improve knowledge exchange, encourage innovation, and address underlying socioeconomic issues (e.g., land tenure; sector demographics etc.).

### 3.7.4 Looking ahead (N6)

The following would be useful to provide an improved assessment capability in CCRA4:

- Regular systematic survey on the uptake of adaptation practices in the UK, including for different farming/forestry systems and locations, and integration with related land use datasets such as the National Forestry Inventory or agricultural census data.
- Application and trialling of near-term climate forecasts as related to productivity issues.
- Climate information tailored to crop breeding programmes (see also Risk N9).
- A more comprehensive assessment of climate resilience and robustness of different land use options in the context of changing water availability, including risks and opportunities for both rainfed and irrigated farming systems.
- Address key knowledge gaps – e.g., grasslands (see agenda of Kipling *et al.*, 2016).
- Better integration of adaptation pathways with Net Zero pathways.
- Combined use of climate projections with socioeconomic scenarios to place UK domestic production in an international context.

## 3.8. Risks to agriculture from pests, pathogens, and INNS (N7)

- Pests, pathogens and invasive non-native species present serious risks to agricultural productivity, with consequences for livelihoods and businesses. Large-scale outbreaks or invasions may also have ramifications for food security.
- The combined risk factors (climate and non-climate) clearly suggest that the magnitude of this risk is increasing from medium (present) to high (future).
- Current institutional risk assessment procedures provide some adaptive capacity that acts to reduce the risk to a lower level at present and this will also have benefits in reducing risk in the future.

- There is a need for additional urgent action to improve preparedness, including improved surveillance, especially in the context of the need for enhanced international co-ordination following EU-exit and associated trade agreements.
- The role of Integrated Pest Management (IPM) should be further supported in an adaptation context to help avoid the various negative consequences of excessive pesticide use.

## Introduction

Although originally defined separately for this CCRA, risks to agriculture from pests, pathogen and invasive non-native species (INNS; see Glossary for definitions) have been combined together because climate change tends to blur the distinctions (e.g., some INNS are vectors for pathogens) and adaptation requires an integrated approach to biosecurity and surveillance.

The relationship of this risk with both climate and climate change is multi-faceted. Each problem species or micro-organism has its own specific climate sensitivities that can favour their increased incidence. This includes parameters related to maximum and minimum temperature, moisture (both precipitation and specific/relative humidity can have an influence), and potentially wind (notably direction); these typically act in combination and also are related to their duration or frequency. In addition, socioeconomic factors are highly influential, including both management factors at farm level and large-scale drivers such as trends towards globalisation of trade and travel.

The combined risk factors (climate and non-climate) clearly suggest that the magnitude of this risk is increasing, despite ongoing scientific challenges in attributing the relative influence of individual risk factors. In aggregate, across the range of known risks (only a limited set of which have been currently quantified), we assess this risk as increasing from medium (present) to high (future) based upon expert opinion, with the risk magnitude also being proportional to the degree of climate change. We also recognise limits on our knowledge of this climate risk relationship, more notably because the most severe outbreaks are typically related to extreme or anomalous climate conditions.

The current institutional risk assessment procedures provide some adaptive capacity that acts to reduce the residual risk to a lower level at present and this will also have benefits in reducing residual risks in the future. However, future climate change, especially in a world with a higher magnitude of climate change, will almost certainly bring new risks that challenge current procedures. There is therefore scope for additional urgent action to improve preparedness, including enhanced surveillance and horizon scanning, and to address the increased prospect of emergent risks (especially from novel pathogens) through additional contingency planning. The timing of emergent risks is especially uncertain; therefore, contingency planning can have benefits even for the present-day.

It is very likely that EU-exit will have important implications for this risk through modified trade arrangements and associated adjustments to regulatory regimes, but details on these changes remain very limited at present. In addition, we have very limited information on how COVID-19 may modify this risk beyond a general increased public awareness of the severe consequences that arise from spread of pathogens.

### 3.8.1 Current and future level of risk (N7)

#### 3.8.1.1 Current risk (N7)

There are important uncertainties regarding the changing incidence of pests, pathogens and INNS (see below), although the evidence is at least strong enough to establish that the magnitude of their combined risk is already a significant challenge for the agriculture sector. In addition to academic publications, evidence is provided by current status of pest risk assessments, together with similar assessments for pathogens and INNS, which in many cases identify climate as a contributing risk factor. Nevertheless, in terms of an aggregated assessment in our view the evidence remains incomplete and heavily based upon specific examples rather than a more complete assessment of the overall risk.

The risk from pathogens has been conceptualised in terms of a disease triangle (Fones *et al.*, 2020), involving the interaction of host presence/susceptibility (including factors such as genetic resistance and plant health), pathogen virulence (factors such as population size, genes, sporulation, lifecycle and selection pressures), and environmental factors (temperature, humidity, light, soil nutrients, air pollution). Climate factors have been particularly highlighted with regard to the changing incidence of some crop diseases. For example, ADAS (2019) analysed septoria and yellow rust in winter wheat with the aim of developing a climate change indicator and found large interannual variability in disease incidence which appears to be linked with variable weather conditions, with septoria peaking in 2012, 2016 and 2017, and yellow rust peaking in 2014 and 2016. Field trial data also indicates that during these peak years, untreated crops had significant lower yield than treated crops (typically 3.6 t/ha compared to 5 t/ha), which demonstrates the negative impacts that disease outbreaks can have on agricultural production (in combination with other factors already identified for Risk N6). These impacts can incur large damages for the sector: for example, the greatest threat at present for the wheat crop is *Septoria tritici blotch* (STB), which is dispersed by wind-blown spores and, based upon assumed 5-10% harvest losses has been estimated in an EU study to cost UK growers alone around €120-240m per year in yield losses (Fones and Gurr, 2015).

Regarding pathogens in livestock, considerable emphasis has been placed recently on the risk of Bluetongue virus which affects cattle/sheep and is spread by the bites of midges (*Culicoides* species), acting as a vector. Transmission has been linked to the influence of higher temperatures in accelerating the midge lifecycle, abundance, and range, and hence virus development (Jacquot *et al.*, 2017). Outbreaks are most frequent in late summer when midge populations peak. An outbreak in the UK in 2007 was linked to prevailing southerly winds from France (Jones *et al.*, 2019), and the virus has also been detected in cattle imported from France into the UK. Outbreaks in other European countries have resulted in severe economic impacts (e.g., Gethmann *et al.*, 2020).

Much of the southeast UK already has suitable temperatures for bluetongue transmission, but suitability is currently at a lesser level for areas further north and west. Analysis at 10 farm sites in southern Ireland has shown that *Culicoides* abundance was highly correlated with ambient temperatures in the region, and the species responsible for both Bluetongue transmission and the more recent risk from Schmallenberg disease (SBV) were present (Collins *et al.*, 2018). Wind patterns are an important factor in assessing risks through *Culicoides* redistribution, and hence may transport pathogens from continental Europe to the UK or southern Ireland to Northern Ireland. For example, it has been proposed that the re-emergence of SBV in Ireland in 2016 was a result of favourable

easterly wind conditions that could have facilitated the transport of virus-infected *Culicoides* into Ireland from neighbouring countries (Collins *et al.*, 2017).

Socioeconomic factors interact with climate factors to also influence the magnitude of risk, most notably at macro-scale through globalisation and the changing pattern of trade. At farm or landscape scale, management factors can also have a key influence. Analysis for the UK Plant Health Risk Register has highlighted inherent vulnerabilities related to current methods of production. For example, the impetus to maximise crop yields has in some cases meant a preference for one dominant variety/cultivar or only a small range of varieties/cultivars. Hence, if this selection becomes susceptible to certain pests or pathogens, then there is limited capacity for a fallback to more resistant types.

The emergent risk from new pathogens is of particular concern. An example of such a risk in continental Europe is that now associated with a virulent but undocumented disease of kiwifruit in Italy. Currently, the exact causes of the disease remain to be established but there is a possibility that the syndrome is a physiological effect at least partially associated with another incidence of infection by *Phytophthora* species which are typically more prevalent in less aerobic, waterlogged conditions.

CCRA2 recognised the increasing climate-related risk from INNS and new evidence further demonstrates the scale of the problem. The Environmental Audit Committee (2019) report on Invasive Species identified INNS as one of the top five threats to the UK's natural environment. Previously, analysis has estimated total costs to the GB economy of £1.7 billion per year (£1.3 billion to England, £0.24 billion to Scotland and £0.13 billion to Wales) (Williams *et al.*, 2010).

In assessing risk from INNS, distinctions between introduction and establishment as compared to spread and consequent impact become important as the magnitude of impact increases at each step. Most INNS are introduced by human agency and prevailing conditions may then encourage establishment and spread. Pathways define the routes for introduction and subsequent spread. The formal international UN CBD definition of INNS emphasises human agency, but climate change acts to challenge this legal convention by modifying 'natural' species ranges. The most recent GB Non-native Species report card (2017) does recognise that a small but increasing proportion of non-natives established since 1700 have been due to 'natural movements'; in this case the risk is related to natural spread of a non-native once it has become established in a new biogeographic domain (for example, spread of harlequin ladybird or insect vectors hosting Bluetongue virus to the UK from continental Europe where it is non-native). Furthermore, the notion of a 'native' species can be challenging to apply in a consistent format, including variations across the different nations of the UK. In this assessment, we have assumed that the primary risk of a direct climate change effect on INNS is associated with natural spread and establishment from continental Europe and therefore that it will affect southern UK areas first. By contrast, an indirect climate change risk is associated with the wider group of INNS that are introduced by human agency and for which a favourable climate then further supports establishment and spread in the UK; this may occur throughout the UK and from throughout the globe (temperate Asia is a notable source of concern).

A general description of risks from INNS in the UK is provided for Risk N2 as informed by reports on existing threats from the GB Non-native Species Secretariat and horizon-scanning activities carried

out for both GB (Roy *et al.*, 2014a), Ireland (Lucy *et al.*, 2020), and Europe (Roy *et al.*, 2019) that evaluate potential threats that may materialise in the next few years.

However, the risk from damaging non-native species continues to change, requiring regular updates and refinements to risk assessments. A notable example, because of its potential to cause serious disruption to agriculture and horticulture (primarily fruit and vegetables), is the brown marmorated stink bug (*Halyomorpha halys*) which is native to Asia but spreading globally (Stoeckli *et al.*, 2020). After inadvertent introduction into Switzerland this species has been recently confirmed in south-east England although it is considered unlikely to reach more than one generation per year, which would prevent it at present from reaching harmful levels.

Evidence for risks to agriculture are especially notable when INNS are associated with damaging pathogens. For example, climate change, and especially the trend to warmer winters in recent decades, has been identified as a risk factor with regard to species such as *Candidatus Liberibacter solanacearum* (Lso) which is a pathogen primarily spread by insect vectors that can damage solanaceous crops (potato etc.) and has also been found on carrot and celery in Europe, including recently in Scotland (Sumner-Kalkun *et al.*, 2019). Similarly, for *Xylella fastidiosa* which is also a pathogenic bacterium spread by insect vectors particularly targeting vines and olives, but with potential to spread to other crops that are more common in the UK (White *et al.*, 2019).

In addition to direct impacts on agricultural production, INNS may also have indirect effects through modifying key ecosystem functions. A notable example of this is the risk to pollinators, which are essential for some crops, and already exposed to multiple pressures including from climate change and parasites (see Risk N1). Some INNS present an additional risk to pollinators, as for example with the Asian hornet which was first detected in the UK in 2016 (most probably transported through trade from China to France) (Keeling *et al.*, 2017), and because of its extensive dispersal ability has made annual incursions in England every year since. Another example would be the increased presence of the New Zealand flatworm and Australian flatworm which have now become widespread in areas within its thermal range of 0-20°C, especially in Scotland and Northern Ireland. These invasive flatworm species arrived on imported plants and prey on the native earthworms that have a key role in soil cycling, primary productivity and ecosystem functioning, with the potential for significant detrimental effects for agricultural production (Murchie and Gordon, 2013).

### 3.8.1.2 Future risk (N7)

Although knowledge has generally improved since CCRA2, investigations of climate change risks still concentrate on a few crops and pathogens. Similarly, analysis of uncertainties in crop disease models remains limited, although there is now increased use of climate model ensembles to quantify uncertainty in some crop disease projections and tools are now also being developed to explore disease dynamics at the landscape level (Newberry *et al.*, 2016).

Climate will act in combination with socio-economic drivers to determine the magnitude of risk. This includes further changes in the pattern of globalisation and trade patterns, together with the scale of active surveillance adopted and pro-active intervention to prevent dispersion of problem species or pathogens to new countries or regions. It is also likely that some patterns and types of land use

patterns, such as large-scale monocultures, may facilitate spread of some pests or pathogen vectors, due to a lack of competitors. In other cases, trends towards increased use of enclosures (e.g., polytunnels) may also be a risk factor because the modified microclimates may favour pest/pathogen increase, although with enhanced biosecurity such spaces may be able to better avoid establishment of problem species.

In general terms, the trend towards warmer and seasonally wetter conditions, most especially in winter months, is very likely to favour increased risk from some existing pests and pathogens (Stetkiewicz *et al.*, 2019). In addition, increased temperatures occurring due to climate change imply increased potential risk due to relationships with increased pathogen genetic variation and virulence, and hence for emerging pathogens (either as a new pathogen or a previously known pathogen in a new place or host), notably from fungal and oomycetes crop pathogens (Fones *et al.*, 2020).

Warmer temperatures are associated with increased over-winter survival of pest species or some pathogen vectors, and wetter, more humid conditions favour greater dispersion of many pathogens, such as *Fusarium pseudograminearum* or *Phytophthora infestans*. Other changing climatic risk factors may include increasing atmospheric CO<sub>2</sub> concentrations or changing wind regimes but evidence on these additional factors is very limited. Also, changing patterns of solar radiation can influence the spore survival viability of some pathogens, with greater radiation acting to reduce risk (e.g., *Phytophthora infestans*: Skelsey *et al.*, 2017), hence trends towards increased solar radiation in many parts of the UK as shown by UKCP18 may act to counter other climate parameters acting to increase risk. In each case, changing seasonal patterns will determine the aggregate risk in combination with the changing host plant growth cycle. For example, an increase in frequency of warm humid summers, as characterised recently by 2019 (in contrast to the warm dry summer of 2018) would imply an increased frequency of high-risk conditions for pathogens such as *Phytophthora infestans* which causes severe problems with late potato blight in the UK. Using the UKCP18 12km spatial ensemble projections, analysis has shown an increase in the warm humid conditions that are conducive to potato blight; based upon regions where most potatoes are grown at present, the 2070 risk threshold exceedance may increase by 70% in East Scotland and between 20 and 30 % across the East of England, the Midlands and Yorkshire and the Humber (RCP8.5 scenario: Garry *et al.*, 2021). Analysis by Skelsey *et al.* (2016) has also indicated that incidence of late potato blight may actually shift seasonally to increase in the first half of the growing season and decrease in the second part. Early potato blight is rarely reported at present in the UK but becoming common in Europe, hence with future projections indicating that parts of the UK will have a climate that has some of the same current climate features as continental Europe then early blight may also become of greater significance.

Whilst the life cycle of some pathogens will be enhanced by increasing temperatures, in other cases they will become more constrained, hence the future incidence of disease is likely to increasingly diverge from present-day patterns, especially at higher magnitudes of warming. For example, potato cyst nematode (PCN) species have different temperature optima for various life cycle stages which is expected to modify their distribution (Jones *et al.*, 2017). By using a PCN life cycle model guided by experimental data, risks to potato crops from three PCN populations (*Globodera pallida* (Lindley); *G. rostochiensis*; *G. pallida* (S-Fife)) have been investigated (Skelsey *et al.*, 2018). Results showed

temperature changes could result in increased survival to female maturity for all three PCN populations, with greater increases expected for Scotland, followed by Wales then England. The largest projected increases in Scotland were for *G. pallida*, whereas *G. rostochiensis* showed the largest increases in Wales and England. Implications for adaptation from this study are discussed in section 3.8.3

The changing incidence of crop disease has been recently reviewed in the context of the new data from UKCP18, with specific emphasis on Wales although the findings also often have wider applicability and will vary depending on different environments (Barrow *et al.*, 2020). Potential increases in incidence have been highlighted for yellow rust, take-all, and eyespot; in the case of eyespot, this is associated with early sowings and wetter winters, both of which are likely to increase with climate change. Warmer winters and increased winter rainfall (which also acts to limit access to the land as required for some control measures) may also increase the incidence of brown rust in wheat and of net blotch in winter barley crops, whilst the risk of rhynchosporium is likely to remain high for crops of winter and spring barley in Wales. An increase in heat stress and drought stress in summer could also have adverse impacts through increased disease outbreaks, including for ramularia. Conversely a decrease in average summer rainfall is likely to reduce the incidence of Fusarium Head Blight (Skelsey and Newton, 2015) and a possible shift to earlier sowing in autumn may reduce the risk of mildew in winter barley. For oil seed rape, diseases such as club root and Verticillium stripe may also become an increased risk, although this is another topic requiring further research.

An under-researched issue that may be associated with a further increase in risk is larger-scale patterns of crop planting across multiple farms at landscape or region-scale. This pattern of crop connectivity is a consequence of land use decisions, including the aggregated effect of autonomous responses at farm level that may encourage a larger-scale trend towards similar crops or monocultures in a region, as influenced by socio-economic factors (notably market prices for crops). In terms of the changing geographic risks of late potato blight in Scotland, these factors have been shown to have a strong influence (Skelsey *et al.*, 2016).

For livestock farming, the increased risks from parasites due to warmer, wetter winters remains a major concern, and although more evidence is becoming available there are still important knowledge gaps. CCRA2 reported on recent research showing the increased risk of fluke which prevails in wetter pastures and is likely to be an increased risk due to milder winters (with a reduced frequency of frosts that constrain fluke populations), particularly affecting livestock that remain outdoors for more of the year due to a longer growing season. *Teladorsagia circumcincta*, one of the most common and economically-damaging endemic parasites for sheep in the UK is projected to increase in a warmer climate, with Fox *et al.* (2018) inferring that the non-linear relationship with temperature could indicate that a threshold-related 'tipping point' is reached where parasite burdens abruptly increase, leading to high-intensity parasite outbreaks. Parasitic gastroenteritis is one of the most cost-effective and feasible diseases to control in Scottish sheep, but ineffective parasite control is also very likely to drive up GHG emissions from livestock (primarily methane emissions).

Changes in climate that include increased winter rainfall and high moisture levels may also exacerbate existing poor indoor ventilation within buildings, which are likely to increase the incidence of respiratory disease in housed livestock. *Haemonchus* infection of sheep was typically confined to southeast England but has recently become widespread whilst *Trichostrongylus*, which was traditionally a problem for lambs in the autumn, is now occurring earlier in the summer and persisting for longer during mild winters (Rose *et al.*, 2016; Barrow *et al.*, 2020).

Blowfly populations are a severe threat to livestock with a distinct peak in risk during the summer months. At present, the usual blowfly strike period, during which negative impacts are mostly focussed, extends from May-September, but in lowland areas when the prevailing weather is unfavourable this risk period can extend from March to December. Projections showing continued climate warming will therefore mean that this extended risk period becomes more prevalent across the UK and may even extend throughout the year in lowland locations (Rose and Wall, 2011).

Regarding bluetongue transmission, in climate projections reaching global warming of between approximately 3.2°C and 5.4°C at the end of the century<sup>19</sup>, all but the Highlands of Scotland would be warm enough for rapid spread of the virus by the 2080s (Jones *et al.*, 2019). The same analysis also found that in England and Wales, an outbreak might be expected in any year by the 2070s assuming the same RCP scenario, compared to once every 20 years now.

An additional risk factor for livestock for which we have limited evidence is the potential increase in toxic weeds. Some weed species are likely to be favoured by trends to warmer, wetter winters and this may act to limit forage quality. However, some of these species are also important in terms of their wider role in agro-ecosystems, such as for example with ragwort which is important for pollinators, therefore control of weeds will require appropriate control measures and adaptation of good practice to avoid negative side-effects.

Confidence is low for projecting future climate change risks from INNS because of the complex species-related interactions between climate change and changing socioeconomic drivers. There is an expectation of increased risk due to further developments in globalisation and world trade, but a key uncertainty is the degree to which international agreements will be universally and rigorously enforced. At higher magnitudes of climate change there is a much greater risk of new INNS becoming established in the UK and, in some cases, for emergent risks to develop as ‘unknown unknowns’ regarding the introduction of a new problem species on which we currently have a lack of knowledge, especially regarding the vulnerability of key UK crops or farm animals.

There is a high level of scientific consensus that risks from invasive species are in general expected to increase due to climate change (e.g., Bellard *et al.*, 2018; see also Risk N2). Agriculture may be especially susceptible to damage from INNS where production has favoured extensive areas of monoculture with plants favoured by the invasive species but where any natural predators have been lost therefore reducing options for control and potentially facilitating larger increases and spread of the invasive.

---

<sup>19</sup> A subset of CMIP5 climate projections selected to sample the the multi-model ensemble driven by the RCP8.5 concentrations pathway. 3.2°C and 5.4°C warming represents the 5<sup>th</sup> to 95<sup>th</sup> percentile range.

As the life cycles of many INNS are especially sensitive to warming, climate suitability will expand across the UK for an increasing number of problem species. For example, Bradshaw *et al.* (2019) showed that risk from the tobacco whitefly (*Bemisia tabaci*) becoming established in the UK would be much greater in a 4°C scenario compared to a 2°C scenario (based upon inferences from the high climate change scenario RCP8.5 and CMIP5 climate models), and also with greater risk in the south of the UK compared to the north. This problem species is currently only a problem in the UK in glasshouses but is present outdoors in France. This study showed minimum temperatures in summer were a key factor determining its establishment outdoors, and with UKCP18 and CMIP5 indicating a clear trend for these to increase, this INNS can be inferred to become an increased future risk for UK cropping.

Nevertheless, more detailed projections of change in risk, such as at sub-UK level require further research. Large-scale climate modelling of the distribution of invasive species shows that there is often a lack of clear consensus on the pattern of dispersion. Although analyses of INNS are most common for plants and invertebrates, meta-analysis suggests that larger shifts may be associated with invertebrates and pathogens whereas plants and vertebrates may be more generally associated with reduced range sizes (Bellard *et al.*, 2018). Species distribution models, when validated against other data, can provide useful predictive capability for some INNS, such as the Asian hornet, indicating there is a good potential for these to be used more regularly when updating risk assessments (Barbet-Massin *et al.*, 2018).

In addition to INNS, as highlighted in previous CCRA there is also the likelihood of existing established non-native species becoming more invasive due to climate change (sometimes referred to as 'sleepers'), although there still remains very little evidence on this issue. This includes the prospect that pests may become an increasing problem in a new region or for longer periods, for example cabbage root fly in Scotland, and that changes in life cycles can introduce greater unpredictability in pest forecasts. This may result in more spraying, with consequent negative impacts on non-target species.

An additional risk factor that also needs to be considered is evolving pesticide resistance. In combination with the effects of climate change that include longer activity period and increased overwintering survival, which may produce more damaging generations for multi-voltine species, stakeholder and expert feedback into the CCRA process has indicated a shared view that pesticide resistance may become a significant risk multiplier unless alternative control strategies are available.

### 3.8.1.3 Lock-in risks (N7)

No specific lock-in risks have been identified, however, lock-in may be associated with inaction because once diseases are established (especially INNS), they are difficult and costly to eradicate, and can cause large economic costs. Hence, provided that the current risk assessment procedures remain dynamic (including continued use of horizon scanning) and are open to the possibility of changing risk factors or emergent risks then lock-in effects should be limited. This may require enhanced communication to improve awareness of changing risks, including that new introduction may have different impacts than in their native region.

#### 3.8.1.4 Potential thresholds (N7)

Climate thresholds are known to be an important factor in the establishment and spread of pests, pathogens (including vectors), and INNS, and these also define their scale and changing speed of impact. For this reason, CLIMEX-type models based upon key bioclimate metrics for individual problem species or micro-organisms are often used in risk assessments to assess changing climate exposure. In addition, some risk assessment procedures already include and are activated by known climate thresholds, such as the combination of minimum temperature and humidity for late potato blight risk (Smith periods), including more recent investigation to refine this assessment (e.g., Hutton criteria: Dancy *et al.*, 2017). Some research in Europe has already explored the use of multivariate thresholds to help understand multiple climate parameters, as for example with brown rust in wheat (temperature, humidity, and precipitation thresholds: Junk *et al.*, 2016).

As referred to above, some pathogen burden risks for livestock may have key thresholds that define a tipping point beyond which an abrupt increase in high-intensity outbreaks may occur (Fox *et al.*, 2018). For INNS, thresholds are especially relevant in understanding the initial risk of establishment, often related to minimum temperature, and for the speed and extent of spread, which can include other climate factors, although these thresholds are specific to each INNS and can also depend on other factors (e.g., land use and native biodiversity).

The CCC Thresholds study investigated the influence of higher temperatures on incidences of the sheep parasite *Haemonchus contortus*, and the implications for lamb production, using frequency of exceedance of daily mean temperature of 9 °C (Jones *et al.*, 2020). The study found that as an average across the UK the development season for this parasite increases from 171 days in the baseline period (2001 to 2010) by approximately 30 days under a 2°C scenario, and 60 days under a 4°C scenario (both derived from the high climate change scenario RCP8.5). Current average development seasons have geographic distinctions (England 179 days; Wales 164 days; Scotland 127 days; Northern Ireland 155 days) therefore there is a likelihood of greater increases in those areas which currently have a shorter season, most notably in the uplands. For the UK as a whole, baseline annual economic losses for this parasite have been estimated at £81m/year (around 7% of total production value of lamb). Under the 2°C scenario used by the Thresholds study, losses increase to £97m/year, while under the 4°C scenario they reach £113m/year which would be 10% of present lamb production value (proportionate increases are similar across each country of the UK).

#### 3.8.1.5 Cross-cutting risks and inter-dependencies (N7)

In addition to the severe implications for agricultural productivity, there are also in some cases important cross-cutting interactions with forestry, biodiversity, and human health, requiring a co-ordinated risk reduction strategy. Potential implications also occur for landscape character (Risk N18) because large-scale outbreaks can modify the visual appearance and other amenity value associated with specific land uses. Control of pests, pathogens and INNS involves important interactions also with biodiversity. For example, as previously identified, some weed species that may be agricultural pests can have wider importance, such as for pollinators (e.g., ragwort). In

addition, if control measures involve the increased use of pesticides, including new types of pesticide, there can be additional risks both to water quality and soil quality.

#### 3.8.1.6 Implications of Net Zero (N7)

The Net Zero scenario places a strong emphasis on improved productivity for crops, livestock and forestry, whilst also emphasising the importance of best management practices. However, there is presently a rather wide variation in the efficiency and effectiveness of management practices in the UK, therefore the current reality is rather distinct from an optimised scenario. Our assessment is that an over-emphasis on productivity without due regard for the need for associated good management practice, such as may occur with crop monocultures, may act to increase negative impacts when outbreaks do occur, including both for GHG emissions and wider environmental impacts (e.g., biodiversity; soil quality; water quality). Similarly, research on changing burdens of livestock parasites has shown a considerable additional potential risk to increase GHG emissions (Houdijk *et al.*, 2017; Fox *et al.*, 2018).

Further work is therefore required to assess the viability of the predicated productivity gains outlined in the Net Zero pathway in the context of an increased climate-related risk from pests, pathogens and INNS. This should also include the effects from additional deployment of risk reduction measures, as will probably be required to manage the increased climate change risk and including adaptation strategies such as modified planting periods and animal stocking schedules (indoors/outdoors etc.) together with requirements for diversification to increase overall resilience of production systems and new biosecurity systems.

#### 3.8.1.7. Inequalities (N7)

As described for Risk N6, negative impacts on production can have consequences for agricultural livelihoods, whilst also potentially affecting food availability and price in the case of the most severe outbreaks. This can potentially affect the more vulnerable groups in society. However, no specific evidence on societal inequality issues associated with climate change acting through pests, pathogens and INNS risks has yet been documented. See Risk N2 for inequalities related to risks to terrestrial habitats and species from pest, pathogens and INNS.

#### 3.8.1.8 Magnitude scores (N7)

Magnitude categories (Table 3.23) are based on expert judgement of existing/expected impacts on production outputs (guided by existing risk assessments when available) due to the limited availability of quantitative data for this topic. Confidence is low for future risks due to possibility of emergent risks although it is medium for known risks with clear climate sensitivity (e.g., fluke, Bluetongue, late potato blight). This climate sensitivity provides the rationale for elevating the risk magnitude from medium at present to high under each of the future pathways.

**Table 3.23** Magnitude scores for risks to agriculture from pests, pathogens, and INNS

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium	High	High	High	High
	(High confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Northern Ireland</b>	Medium	High	High	High	High
	(High confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Scotland</b>	Medium	High	High	High	High
	(High confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Wales</b>	Medium	High	High	High	High
	(High confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)

### 3.8.2 Extent to which current adaptation will manage the risk (N7)

#### 3.8.2.1 Effects of current adaptation policy and commitments on current and future risks (N7)

##### 3.8.2.1.1. UK-wide

The general policy context for this risk is the same as Risk N2 and therefore referenced more fully in that section, including relationships to international agreements. Established risk assessment procedures are in place for pests, pathogens, and INNS, covering both existing and new risks and including climate as a key factor. In each country, national adaptation plans provide continued support for these procedures and biosecurity measures. However, as detailed in N2 these plans cannot be regarded as fully robust because they do not define any additional measures based upon the changing risk from climate change, especially if the world were to follow a higher climate change trajectory, such as in a 4°C world. This issue is of particular concern because the likelihood of new emergent risks increases in proportion to the magnitude of climate change and may also be further exacerbated by interactions with socio-economic drivers such as further expansion of trade and globalisation of markets. Experience has indicated that emergent risks are especially notable threats

because they can challenge existing protocols that may take a lengthy period of time to re-negotiate.

The UK Plant Health Risk Register records and rates risks to UK crops, trees, gardens, and ecosystems from plant pests and pathogens, including risk mitigation and new actions to manage or reduce risk. The 2019 EU Plant Health Regulations, which include tighter controls on the import and movement of plants and plant material, have now been transposed into national law. Livestock risk assessments for known pests and pathogens (e.g., Bluetongue) are also in place. For animal pests and diseases, the Animal and Plant Health Agency (APHA), which co-ordinates activities across the UK, acts to monitor notifiable and emerging outbreaks worldwide (supported by analysis capability at the Pirbright Institute) to provide early warning, including risk of entry through trade or wildlife movements, and APHA also conduct collaborative horizon-scanning assessments and information-sharing activities internationally.

The risk assessment process is currently in transition to a new system which aims to provide both improved local information and better coordination linked to best practice guidance. This new system should include better recognition of climate change.

The 2015 Invasive Alien Species Regulation (EU) 1143/2014 has provided a regulatory framework for the prevention and management of the introduction and spread of INNS, providing a more consistent approach across countries. As required by the EU regulations, in May 2019, the UK Government published its comprehensive pathway analysis, identifying 10 priority pathways for unintentional introduction, one of these being horticultural escapes into the wider landscape. Defra has also recently commissioned research to investigate public attitudes and awareness of non-native species (Creative Research, 2018). The Invasive Alien Species (Enforcement and Permitting) Order 2019 introduces enforcement provisions, offences and penalties needed to comply with the requirements of the EU Invasive Alien Species Regulation. It gives conservation agencies and the police and border force officials new powers to address Invasive Alien Species issues in England and Wales at an early stage, and similar legislation for Scotland is now being developed.

Adaptation policies at UK level and for the DAs generally aim to further support existing procedures and ongoing research to improved information and awareness, but do not provide specific actions for agriculture. Therefore, whilst recognising the importance of the issue, the 25YEP for England and current UK NAP do not explicitly reference target outcomes for risk reduction for pests, pathogens or INNS.

Similarly, in Scotland the SCCAP2 does not include specific new actions for agriculture but does provide a commitment to continue to develop and expand the knowledge base, whilst identifying scope for a new potential indicator to record absence of INNS as complement to the current indicator on presence of INNS.

In Wales, the national adaptation plan ('Prosperity for all: A Climate Conscious Wales') emphasises the importance of existing measures and ongoing monitoring whilst also highlighting further efforts to improve awareness and guidance through the Invasive Non-Native Species (INNS) Portal. Additionally, Area Statements identify opportunities for the control of INNS, and to enable collaborative action on the ground. The Wales Animal Health and Welfare Framework aims to

address increased risks related to pests and pathogens for kept animal health (and associated public health issues) but although climate change is recognised as a key factor, the framework does not make explicit reference to specific climate change risks or adaptation actions to manage these risks.

The Northern Ireland Government assessed progress from their first Invasive Species strategy (2013) in 2017 and stated that the majority of targets within the 30 key Actions had been achieved and steady progress was being made towards non-time limited targets. In 2018 the Invasive Alien Species implementation plan was revised. The importance of ongoing biosecurity and surveillance for ensuring the vitality of the agriculture sector is also strongly recognised in Northern Ireland, although again now new measures specifically related to climate change adaptation have yet been defined.

The UK has agreed to meet international commitments to control INNS through the Bern Convention and UN CBD. The Aichi Targets, which fall under the CBD, included a commitment that by 2020 INNS and their pathways would be identified and prioritised, with priority species controlled or eradicated, and pathways managed to prevent species' introduction and establishment. However, in 2019 the UK Government has admitted that progress on meeting this target was "insufficient".

The GB Non-Native Species Secretariat (GBNNSS) coordinate work across England, Wales and Scotland, including a GB-wide strategy (latest version published in 2015) and report card (GBNNSS, 2017). Northern Ireland works on a whole-island basis for INNS with the Republic of Ireland in an All-Ireland Forum, but there are also plans for further integration into a UK Non-native Species Secretariat. Risk assessments are a key component of strategic planning and regulation, and if necessary, for legislation to reduce the risk of entry. Pathogens are not currently included within the INNS strategy, although an inquiry by the Environment Audit Committee (2019) of the UK Parliament recommended they should be included. The 25YEP for England and UK NAP has a goal and indicators related to tackling INNS through the Invasive Non-native Species Strategy. However, currently species that arrive in the UK due to climate change are not classed as 'invasive', and so are not included in the Strategy.

As identified in previous CCRAAs and by the CCC, the current definition of INNS is based upon their transfer beyond their native regions by human agency rather than when migration is assisted by a changing climate. This distinction is likely to have increasing ramifications for definition of, and actions against, INNS as they become increasingly assisted in their movements by a changing climate. A prominent example here would be the continued climate-assisted dispersion of some *Culicoides* (midge) species that can act as pathogen vectors, such as for Bluetongue disease, and which based on the current definition would not be included in current INNS policies but through animal health risk assessment.

Approaches to prevent the establishment of INNS include closing down pathways, enhancing biosecurity at ports and borders, raising public awareness and preventing secondary transfer, horizon scanning and risk assessing new threats. As an example, in 2020 strict import and movement restrictions were placed on a range of species to protect against *Xylella fastidiosa*. Since CCRA2, EU-Exit has increased uncertainties in the continued future sharing of surveillance data with EU

countries and organisations. Increasing cross-border trade has also heightened the risk of pests/pathogens entering UK through these pathways.

Work on the UK Plant Health Risk Register has highlighted inherent vulnerabilities in current production systems which are relevant to successful adaptation. For example, some UK crops are focussed on one variety, or a limited range of varieties, which reduces overall resilience because some varieties are more resistant to pests, pathogens or INNS. A prominent example here would be barley where the demands of maltsters/processors has focussed production on a few specific varieties which means there is an increased vulnerability to pests and diseases. As also emphasised below, the sector as a whole needs to develop increased awareness of the changing risks, whilst research is also continuing to enhance disease resistant traits in cultivars.

### 3.8.2.2 Effects of non-Government adaptation (N7)

Land managers and others in the supply chain have an obligation to report incidences, including for specific INNS, and therefore provide a key component of the surveillance system. However, pressures to improve production may sometimes lead inadvertently towards increased risk, for example by trialling new species or practices that may have an especially strong relationship with particular pests or pathogens. In terms of new technology, apps are being developed to promote increased awareness of risks amongst land managers and the public, and information campaigns such as Check Clean Dry for risks from INNS have been successful in raising prominence of the issues.

Integrated Pest Management (IPM) is an approach to risk management employed in some parts of the sector to link and improve the effectiveness of chemical and biological controls by reducing dependency on chemicals (including negative side-effects for biodiversity, soil quality, water quality, human health etc.). Further work to develop and expand this approach in the context of climate change adaptation, including knowledge exchange across the sector, would be very likely to have further benefits, especially with concerns over pesticide side-effects and pesticide resistance. In addition, as use of IPM is effectively voluntary, it is not currently known what the level of uptake is, especially as IPM implementation needs to both recognise market pressures and be cost-effective as well as being supported by good quality evidence and timely expert advice at local and regional scales to ensure effective uptake.

Another important type of initiative that can help build adaptive capacity is through recommendations on plant varieties and breeding, which can include trials on new pest/pathogen resistant varieties and national listing. At present the relationship with changing climate risks is included in advice from organisations such as AHDB and RHS but there is good scope for further development of such initiatives.

Moreover, in the context of the increased emphasis on delivering the Net Zero agenda, there is scope for further development of Integrated Pest Management (IPM) and plant trials/listing to enhance climate resilience and improve productivity and other goals in order to meet the Net Zero target.

### 3.8.2.3 Barriers preventing adaptation (N7)

Despite recent developments in concepts such as sustainable intensification, current agricultural systems tend to place their emphasis for production on intensive monoculture practices. In addition, globalized markets are driving the emergence and spread of new pathogens and INNS, and there is often an over-reliance on chemical applications to control the risk. Related to this are the increase in problematic traits, notably pesticide resistance, which may further exacerbate long-term risks, as exemplified by insecticide resistance (IRAG, 2018). Similarly new strains of fungi are emerging such as triazole-resistant *Z. tritici* in UK wheat, and new pathogens capable of overcoming inbred R genes, as with yellow rust in wheat (Fones *et al.*, 2020). At the landscape scale, loss of key features, such as field margins that can provide natural competitors and disrupt pathogen dispersion is also an underlying problem that has led to increased reliance on chemical solutions neglecting the principle that the most valuable weapon against pests and pathogens are typically a plant's own immune system and natural competitors of the problem species or micro-organism (Rusch *et al.*, 2016; Miller *et al.*, 2017).

Adaptation requires up-to-date information on the threat of establishment or spread to further encourage active surveillance, and complacency may be a concern in areas not previously exposed. It also requires co-operation beyond national boundaries, and this co-operation may be variable. Investigation of disease suppression has shown the importance of early detection and movement controls. For example, FMD controls in place since 2001 limited the bluetongue outbreak that later occurred in 2007, hence, further investment in new research that shows how control measures may be further optimised is likely to be beneficial (e.g., bluetongue restriction zones: Spooner *et al.*, 2020).

For INNS, identifying the actual pathways for invasion can be very difficult, even when assessed post-invasion (Roy *et al.*, 2014a). A review by Essl *et al.* (2015) indicated that throughout Europe, many invasion pathways remain unknown and that INNS can arrive through more than one pathway. Surveillance and control actions typically occur on a sectoral (or even sub-sectoral basis for specialist sectors such as horticulture) therefore actions are not always co-ordinated, and knowledge of changing risks can be variable. The risk may also be exacerbated because in some cases, management of INNS have fallen between multiple responsibilities (see oak processionary moth: Risk N8). Priorities to maintain or increase production can also mean that excessive risks (e.g., regarding material of unknown provenance) can be taken. It has also been suggested by some stakeholders commenting on the CCRA that there may be pressures from some businesses in the agricultural sector to relax regulations in order to enhance trade post-EU-exit or to improve productivity via new species.

These challenges are especially pronounced for emergent risks for which there may be very little information available and for which procedures for international and national (institutional and stakeholder) responses have not been agreed, and this may cause delays in enacting the necessary actions.

### 3.8.2.4 Adaptation shortfall (N7)

Institutional risk assessment procedures for pests, pathogens and INNS in agriculture currently provide some adaptive capacity. This helps to reduce the risk to a lower level at present and this will also have benefits in reducing risk in the future. However, we expect risks to continue to increase in future, including potential for emergent risks, which is therefore likely to present an increased challenge for existing procedures and indicates that there is scope for additional adaptation measures to lower residual risks to an acceptable level. The UK-wide and nation-specific strategies in place at the moment as set out above, do not include consideration of future climate risks including the potential impacts of up to a 4°C rise in global temperature. Confidence for the future is low due to the limited evidence on adaptation and the combined effects of climate and socioeconomic factors for this risk.

### 3.8.2.5 Adaptation Scores (N7)

<b>Table 3.24</b> Adaptation scores for risks to agriculture from pests, pathogens, and INNS			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.8.3 Benefits of further adaptation action in the next five years (N7)

For INNS, as shown by Figure 3.11 it is much more effective to prevent introduction and establishment rather than attempt to mitigate spread and resulting impacts. The same principles apply for averting introduction of problem pathogens.

Further assessment of climate factors in risk assessment would be beneficial in developing early warning systems. Quantitative analysis of climate change on crop pathogens remains limited (field, laboratory, or modelling studies). A more systematic programme of quantitative analysis is therefore required to inform development of disease management plans, such as plant breeding, altered planting schedules, chemical and biological control methods, and increased monitoring for new disease threats. Improved monitoring of pest and disease levels in UK crops and livestock could be used to provide more updated agronomic advice to growers, including best practice guidance on pest/pathogen biosecurity and management strategies. In addition, identification of plant and animal strains or breeds having greater natural resistance may be used in breeding programmes, including new assessments based upon genetic sequencing (e.g., late potato blight: Chen *et al.*, 2018). Enhanced use of modelling studies is also likely to be advantageous in surveillance and control strategies. For example, for PCN risk (Section 3.8.1), Skelsey *et al.*, (2018) found that soil infestation levels would have to be reduced by up to 40% in order to negate projected increases in risk. The same study identified that successful strategies to reduce future PCN risk were found to include advancing the start date of the growing season or modifying planting patterns.

Policy development following EU-Exit also creates an opportunity to further expand the uptake of IPM rather than rely on current voluntary uptake schemes, and to ensure that regulations adopt the principle of non-regression to ensure appropriate safeguards as risk factors change (e.g., international trade agreements). Increased support by government for IPM, including through a proposed National Action Plan, is very likely to be particularly useful in acting against excessive pesticide usage and its harmful side-effects for soil quality, water quality, and through pesticide resistance.

Further tightening plant health legislation in anticipation of increased risks is also likely to be required. The costs of tightening legislation could be i) a reduction in trade due to increased costs and ii) potential restrictions placed on exports from the UK by countries affected by the tightening of plant health legislation.

Evidence from this CCRA and in previous CCRA's suggests a greater priority be given to including climate change within risk assessments, and for this to be validated against changing distribution data for Europe and beyond, and where possible to be used to further investigate the efficacy of different control options. Following the Environment Audit Committee 2019 report, it is also suggested that a greater priority now be given also to a wider public engagement through citizen science initiatives to enhance surveillance. A positive example of this in practice has occurred through networks of bee-keepers to monitor Asian hornet risk (BeeBase, 2021).

### 3.8.3.1 Indicative costs and benefits of additional adaptation (N7)

Consistent with the discussion above, the economic case for further uptake of existing adaptation measures is sound, as evidenced by case study analysis on pests and pathogens (Watkiss *et al.*, 2019): it is much more effective to prevent introduction and establishment rather than attempt to mitigate spread and resulting impacts. However, this additional uptake of measures has an associated resource cost. There is a clear role for public co-ordination of monitoring and surveillance. Previous analysis by SRUC (2013) has identified that investment in monitoring for pests has a high benefit-cost ratio of around 10:1. The Environmental Audit Committee (2019) identified that expenditure on GB biosecurity is ca. £220 million per year, but invasive species only receive 0.4% of that sum (£0.9m). There are also clear benefits from Government investing in information about pests and pathogens – their spread, likely impacts, and treatment methods – as this information flow would not otherwise occur. Whilst a large proportion of the costs (for pests and pathogens) may be borne by private land-owners, public support is likely to be needed where there are local concentrations of economic activity that are threatened by the rapid spread of one of these pathogens in an area (to reduce the much larger costs once pests and pathogens become established). This economic argument is strengthened by climate change risks because the future nature of threats will in many cases be distant from private actors' past experience.

### 3.8.3.2 Overall urgency scores (N7)

<b>Table 3.25 Urgency scores for risks to agriculture from pests, pathogens, and INNS</b>				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Medium	Medium	Medium	Medium

Because of the high projected magnitude for this risk, and the view that additional intervention is required to in the future to manage risk to low levels, in particular to integrate future climate scenarios into existing policies designed to control pests, pathogens and INNS, a 'More Action Needed' score has been assigned across the UK.

As well as enhancements of existing policies to take into account the changing risk due to climate change, improved surveillance and monitoring is required, especially in the context of the need for improved international co-ordination following EU-exit and associated trade agreements; this will require sustainable funding as it relies on a co-ordinated network of station data and part-private initiatives (AHDB pest bulletins; SRUC Crop Clinic in Scotland etc.). This also requires:

- Further development of international monitoring initiatives, surveillance, risk assessment procedures and bio-security measures based upon UKCP18 and other relevant climate change data.
- Enhanced horizon scanning for INNS from Europe and globally based upon changing international trade portfolio.
- Cross-sectoral initiatives for risk assessment and contingency planning using a range of diverse scenarios.

- Evaluation of risk reduction strategies for specific risks including prospects for resilient varieties and the use of increased diversification in plant and livestock species/varieties.

### 3.8.4 Looking ahead (N7)

- Improved risk assessments with space and time dimensions to evaluate changing dynamics of individual pests, pathogens and INNS, together with their changing status regarding prospects for future establishment and spread based upon both climate change and socioeconomic data (e.g., using combined scenario analysis, including land use change).
- Improved spatial profiling of risks including for extreme years to help better understand changing risk factors at a higher resolution across the UK.

## 3.9. Risks to forestry from pests, pathogens, and INNS (N8)

- Pests, pathogens and invasive non-native species present serious risks to forest productivity, with consequences for livelihoods and businesses, and for the multiple ecosystem services that forests provide.
- The combined effect of risk factors (climate and non-climate) indicates the magnitude of this risk is increasing. Across the limited set of known risks, we assess this risk as increasing from medium at present to high in the future.
- Existing risk assessment procedures provide some adaptive capacity which acts to reduce residual risk to lower levels at present. However, the scale of future climate change is very likely to mean new threats emerge that challenge existing measures, especially for pathways of higher magnitude of climate change.
- There is a need for further urgent action to improve preparedness, including enhanced surveillance and horizon scanning, and to address the increased prospect of emergent risks.

### Introduction

Pests, pathogens and invasive non-native species (INNS; see Glossary for definitions) present serious risks to forest productivity, with consequences for livelihoods and businesses, and for the multiple ecosystem services that forests provide. These individual risks have been combined together because climate change tends to blur their specific distinctions (e.g., some INNS are vectors for pathogens), and adaptation requires an integrated approach to biosecurity and surveillance.

The relationship of this risk with climate change is complex. Each problem species or micro-organism has its own specific climate sensitivities that can favour their increased incidence. This includes parameters related to maximum and minimum temperature, moisture (both precipitation and specific/relative humidity can have an influence), and potentially wind (notably direction); these typically act in combination and are also related to duration or frequency. In addition, socioeconomic factors are highly influential, both management factors at forest/stand level and large-scale drivers such as trends towards globalisation of trade and travel.

The combined risk factors (climate and non-climate) clearly suggest that the magnitude of this risk is increasing, despite uncertainty in attributing the relative influence of individual risk factors. In aggregate, across the range of known risks (only a limited set of which have been currently quantified), we assess this risk as increasing from medium (present) to high (future) based upon expert opinion, with the risk magnitude also being proportional to the degree of climate change. We also recognise limits on our knowledge of this climate risk relationship, more notably because the most severe outbreaks are typically related to extreme or anomalous climate conditions.

The current institutional risk assessment procedures provide some adaptive capacity that acts to reduce the residual risk to a lower level at present and this will also have continuing benefits in reducing residual risks in the future. However, future climate change, especially in a world with a higher magnitude of climate change, will almost certainly bring new risks that challenge current procedures, hence, there is a future adaptation deficit. There is therefore scope for additional urgent action to improve preparedness, including enhanced surveillance and horizon scanning, and to address the increased prospect of emergent risks (especially from novel pathogens) through additional contingency planning. The timing of emergent risks is especially uncertain meaning contingency planning can have benefits even for the present-day.

It is very likely that EU-exit will have important implications for this risk through modified trade arrangements and associated adjustments to regulatory regimes, but details on these changes remains very limited at present. In addition, we have very limited information on how COVID-19 may modify this risk beyond a general increased public awareness of the severe consequences that arise from spread of pathogens.

### 3.9.1 Current and future level of risk (N8)

#### 3.9.1.1 Current risk (N8)

In general terms, there is increasing evidence available that the rate at which new tree pests and pathogens are being introduced is increasing, primarily linked to the expansion of trade of timber and wood products, but with climate as an additional risk factor (e.g., Freer-Smith and Webber, 2015; Potter and Urquhart, 2017). Although challenges remain in attributing individual risk factors, we are confident in highlighting the risk of significant damage to forests in the UK which also extends to loss of the multiple ecosystem services that forests provide. This is supported by evidence from several sources, notably Defra pest risk assessments, incidence reporting on disease outbreaks in forestry (co-ordinated by Forest Research), and reports from the GB Non-native Species Secretariat and equivalent forum for Ireland. Nevertheless, forest pests and pathogens typically feature non-linear population dynamics and related feedback effects that currently confound a more complete understanding of changes in risk.

Several high priority pests in the UK Plant Risk Register have been identified with a climate link and strong relevance for forestry interests (risks for woodland biodiversity are assessed in Risk N2). For example, climate has been identified as a risk factor with regard to species such as emerald ash borer *Agrilus planipennis*. Previous CCRA's have highlighted climate-related risks in recent years from *Phytophthora ramorum* and *Dothistroma* needle blight, both of which have implications for conifer

production. *P. ramorum* is a fungal-line pathogen which has continued to spread in the UK, particularly in bioclimatic zones with high year-round moisture levels such as SW England, parts of Wales, Cumbria, SW Scotland and Argyll; however, rates of new larch infection have declined recently except in Wales, which may also be related to local climate variations. Similarly, *Dothistroma* needle blight has continued to spread north into Scotland, and in particular to affect east and north Scotland which have extensive areas of sensitive woodland. This pattern of infection has been linked with increasing precipitation in recent years during spring and summer together with warmer temperatures (Woods *et al.*, 2016). Damage is particularly severe for Corsican pine, but other affected species include lodgepole pine and Scots pine, the latter of which also has considerable amenity and biodiversity value (Brown and Webber, 2008).

Pest status for some species is associated with the damage caused by greater population numbers beyond a sustainable level. This is especially notable for native deer species that have benefited from increased frequency of warmer winters and which in a forest setting can cause considerable damage by browsing young trees. Deer are also very mobile and can range over a large area, as has occurred with the expansion of the red deer population in the Scottish Highlands where deer can move from sporting estates to forestry plantations whilst also preventing natural regeneration, although more evidence is required on these behaviours in the context of climate patterns.

Some syndromes associated with pests and pathogens appear to be due to the interaction of multiple stresses. For example, Acute Oak Decline, which is affecting native oaks in the UK, is principally caused by multiple, interacting bacterial species that degrade inner bark tissues, but the two spotted oak buprestid *Agilus biguttatus* which is an oak borer beetle, is also found to be strongly associated. A recent study has shown how historical episodes of stress, dating back as far as the 1930s may also be important factors and that correlations with climatic variables indicate that diseased trees are less able to take advantage of good growing conditions in the spring and autumn (Reed *et al.*, 2020).

As with agriculture (Risk N7), we have assumed that the primary direct climate change risk for INNS is associated with natural dispersion from continental Europe and therefore that it will affect southern UK areas first, whereas INNS that are introduced directly into the UK by human agency at any location may then indirectly benefit from climate change favouring establishment and subsequent spread. The impact on forestry from INNS is shown by species that have previously become established and have now spread, often aided by the shift to milder winters in recent decades. Pettorelli *et al.* (2019) identified impacts from climate change related movements of animals into new environments in GB since 2008, highlighting several with a woodland impact, including northward expansion of *A. biguttatus* to become established in the Manchester area, and box tree moth (*Cydalima perspectalis*) which has become established in the London area. Another example of a damaging animal INNS is the presence of muntjac deer and sika deer which have both increased in numbers in recent years, aided by the increased frequency of milder winters, to the detriment of the trees in forest plantations on which they browse (Armstrong *et al.*, 2020).

For softwood forestry production, bark beetles present an increased threat through damage caused to tree health and timber quality, notably the great spruce bark beetle (Forest Research, 2021a) which preys on spruce and pine and has become established in Wales, western England and

southern Scotland (not reported currently in Northern Ireland). In addition, the larger eight-toothed European spruce bark beetle (*Ips typographus*) has been recently detected in England (Forest Research, 2021b).

The changing patterns of risk for pests, pathogen and INNS, are strongly influenced by other socioeconomic factors that can facilitate their introduction to the UK and spread to new areas, notably through changing patterns of trade (and particularly through trade related to nurseries). In July 2019, 60 sites across UK were exposed to oak processionary moth (*Thaumetopoea processionea*) caterpillars due to the import of oak trees from the Netherlands and Germany. Warming and escape from natural co-evolved predators has allowed this moth species to expand its range in northern Europe from its original locations in southern and central Europe (de Boer and Harvey, 2020). It is now established in the Greater London areas and is primarily a risk for hardwood species and the multifunctional aspects of forestry management, rather than softwood production, and the caterpillars are a human health hazard (see Chapter 5: Kovats and Brisley, 2021).

In addition, new policy incentives may be further modifying risks. Expansion of trade in wood chips, as supported by policy proposals to increase bioenergy supply as a form of renewable energy, can act to increase the risk of imported material that contains infestations of damaging insect pests, including emerald ash borer beetle, bark beetle, and other *Agrilus* species. Although import regulations into Europe (usually from North America) are quite strict for coniferous wood chips (to control spread of pinewood nematode), they remain more relaxed for deciduous wood chips. This risk is averted by use of wood pellets, as utilised in the UK Drax power stations to meet its bioenergy quota requirement.

### 3.9.1.2 Future risk (N8)

Although knowledge has generally improved since CCRA2, investigations of climate change risk are still predominantly based upon a few pests, pathogens, or INNS, as ‘known knowns’. Therefore, although our knowledge of the underlying processes implies an increased risk from climate change, especially for higher magnitudes of change, confidence in the details remains low. The trend towards warmer and seasonally wetter conditions, especially in winter months, is very likely to favour increased risk from some existing pests and pathogens. However, as with agriculture, higher temperatures also present an additional risk factor through increased pathogen genetic variation and virulence, and hence for emerging pathogens (i.e., a new pathogen or a previously known pathogen in a new place or host), and together with the increased risk of introduction of novel INNS, these emergent risks represent both ‘known unknowns’ and even ‘unknown unknowns’.

Climate will act in combination with socio-economic drivers to determine the magnitude of risk, notably through globalisation and trade patterns. At local level, stand management, including trends towards either monocultures or diversification, will also be highly influential, especially in influencing the landscape-scale dynamics and dispersion of pests, pathogens and INNS through host species connectivity. In addition, changing choice and provenance of tree species (e.g., cherry), use of larger trees, and potentially greater demands for forestry products such as woodchip etc., will also have an important influence on risk management.

Existing evidence is based upon the known risks for individual pests and pathogens. Notable examples include *Ips typographus* (larger eight-toothed European spruce bark beetle), which, in addition to being intercepted in imports, has recently been recorded in England. This species could have severe consequences for the large spruce population in the UK and now has a Plant Health Order providing the basis for obligatory demarcation of outbreaks and associated movement restrictions on forest products. In addition, *Dendroctonus micans* (great spruce bark beetle) and *Elatobium abietinum* (green spruce aphid) both also present an increased risk. For example, risk of more frequent green spruce aphid attacks has been identified as a threat to Sitka spruce growth in west, east and south Wales (Berry *et al.*, 2019). It also seems likely that the increased drought stress expected in many areas of the UK in the future, as indicated by the trend to warmer drier summers in UKCP18, may make trees more vulnerable to pests and pathogen, although again we have limited evidence on these combined risk factors.

The use of exotic species in UK forestry has also been suggested to be an additional risk factor for pathogens (in addition to the risk from such species themselves for native biodiversity – Risk N2). This this can lead to emerging forest disease risk both by facilitating introduction of exotic pathogens and by providing susceptible hosts on which epidemics of native pathogens can develop, as shown by transfer of *Dothistroma septosporum* from non-native species to the Caledonian pine populations of Scotland (Piotrowska *et al.*, 2018; Ennos *et al.*, 2019). It is also likely that some patterns and types of land use patterns, such as large-scale monocultures, may facilitate the spread of some pests or pathogen vectors due to a lack of competitors. It is also possible that initiatives to enhance woodland connectivity by developing contiguous plantations may inadvertently enable spread of some pests and pathogens, unless appropriate counter measures (e.g., stand-scale management planning and diversification) are also implemented. Hence, measures that seek to enhance diversification in silviculture may be a key risk reduction strategy (Ray *et al.*, 2019; see also risk N6). In this context, diversification may conceivably include exotic non-native species as an option based upon a full balanced risk assessment; this may also require changing recognition of native/non-native distinctions in tree species across the different nations of the UK.

Climate change may also have indirect effects through interactions with pathogens. For example, spatial analysis of ash dieback disease caused by the fungus *Hymenoscyphus fraxineus* (commonly called *Chalara fraxinea*) using multiple GCMs and emission scenarios shows how climate change, by affecting host and pathogen separately, may uncouple their distribution and potentially in this case lower disease transmission in some regions of Europe, including the UK (Goberville *et al.*, 2016). Hence, ash may remain a viable future species in woodland ecosystems despite current concerns.

Confidence is low for projecting future risks from INNS because of the complex species-related interactions between climate change and changing socioeconomic drivers (see also Risk N2 and Risk N7). As the life cycles of many INNS are especially sensitive to warming, climate suitability will expand across the UK for an increasing number of problem species. Large-scale climate modelling of the distribution of invasive species shows that there is often a lack of clear consensus on the pattern of dispersion. Although analyses are most common for plants and invertebrates, meta-analysis suggests that larger shifts may be associated with invertebrates and pathogens whereas plants and vertebrates may be more generally associated with reduced range sizes (Bellard *et al.*, 2018).

The consensus view, based upon population increases in recent decades, is that further trends towards warmer winters are likely to increase the prospect of increased damage from deer to forestry production and other services (included carbon storage – see Risk N5), although impacts will also be influenced by local landscape structure (Spake *et al.*, 2020). Impacts will also be more severe in a scenario where deer numbers are not controlled at a sustainable level. This increased risk of deer damage includes both risks from native species and further problems related to the spread of INNS that are already established in the UK, notably muntjac and sika deer.

#### 3.9.1.3 Lock-in (N8)

As forestry decisions are long-term due to the time taken for trees to reach maturity, there is a higher potential risk from lock-in due to poor awareness of long-term consequences at the time of planting. Nevertheless, there is an increased awareness of the long-term issues in the forestry sector, as compared to agriculture, partly due to the legacy of past decisions such as large monocultures of certain species (notably Sitka spruce). This is primarily based upon production criteria, and the resultant implications for wider ecosystems services such as water quality, biodiversity and amenity value. This may mean that there are still contradictions regarding definitions of ‘long-term’ in forward planning: for some commercial plantations this can mean ca.35 years, whereas for some natural woodlands, especially where supported primarily by large old trees, it might be in excess of 100 years. This variation in the level of lock-in risk needs to be accounted for in risk management actions. The challenge for the sector will be therefore both to improve risk assessments to include the changing nature of currently-known risks but also to build in extra contingency to counteract expected emergent risks that are still unknown at present, also recognising that new INNS or pathogen introductions may have different impacts than in their native region.

#### 3.9.1.4 Thresholds (N8)

As discussed in more detail in Risk N2 and Risk N7, there are important climate thresholds (e.g., minimum temperature) related to both the establishment and spread of pests, pathogens and INNS, although these are specific to individual species or pathogens. Threshold-type models using key bioclimate metrics have been employed to assess the changing risks from some species or pathogens, as for example in risk assessments for *P. ramorum*.

#### 3.9.1.5 Cross-cutting risks and inter-dependencies (N8)

In addition to the obvious negative implications for forest productivity from large scale outbreaks, there are also in some cases important cross-sectoral interactions with agriculture, biodiversity, human health (Chapter 5: Kovats and Brisley, 2021), and landscape character (e.g., through loss of visual amenity or aesthetic qualities) including through loss of ecosystem services (Freer-Smith *et al.*, 2015; Boyd *et al.*, 2013). In addition, reduced biomass production from this risk may also have implications for carbon storage/sequestration targets (Risk N5). Pest and disease outbreaks can also reduce the resilience of forests and woodlands to wildfire by increasing fuel loading associated with both standing trees and surface litter. There is also the potential for secondary impacts on water and

soil quality if increased pesticide use, or new pesticide types, are employed to address the changing risk.

#### 3.9.1.6 Implications of Net Zero (N8)

The CCC Net Zero (2020) scenarios place a strong emphasis on woodland expansion combined with improved productivity. As identified above large-scale outbreaks may have implications for LULUCF targets defined for Net Zero by acting against productivity gains. In addition, although the central ('Balanced') CCC Net Zero (2020) scenario emphasises best management practice to avoid negative side-effects whilst enhancing productivity, as noted above there are wide variations in management practices currently in UK forestry as typically related to land owner/manager motivations for woodland creation (see also Risk N6). Hence, an over-emphasis on productivity without due regard for the need for associated good management practice, such as may occur with single-species monocultures, may act to increase negative impacts when outbreaks do occur. Further work is therefore required to assess the viability of the predicated productivity gains outlined in the Net Zero pathway in the context of an increased climate-related risk from pests, pathogens and INNS, including the implications from additional deployment of risk mitigation measures, notably biosecurity and diversification to enhance resilience, and the need to avoid other negative side-effects (e.g., for biodiversity, soil quality, and water quality).

#### 3.9.1.7 Inequalities (N8)

No evidence regarding inequalities associated with climate change were identified in relation to this risk. See Risk N2 for inequalities related to risks from pest, pathogens and INNS.

#### 3.9.1.8 Magnitude scores (N8)

Magnitude categories (Table 3.26) are based on expert judgement of existing/expected climate impacts on production and other forestry services (guided by existing risk assessments when available) due to the limited availability of quantitative data for this topic. Based upon climate sensitivity of known threats we expect this risk to substantially increase with future climate change, and to reach a high magnitude score under all but the lowest future climate change projections. However, confidence is low for future risks due to the interaction with socioeconomic factors and possibility of emergent risks.

**Table 3.26** Magnitude scores for risks to forestry from pests, pathogens, and INNS

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
England	Medium	Med-High	High	High	High
	(High confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
Northern Ireland	Medium	Med-High	High	High	High
	(High confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
Scotland	Medium	Med-High	High	High	High
	(High confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
Wales	Medium	Med-High	High	High	High
	(High confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)

### 3.9.2 Extent to which current adaptation will manage the risk (N8)

#### 3.9.2.1 Effects of current adaptation policy and commitments on current and future risks (N8)

##### 3.9.2.1.1 UK-wide

The general policy context for this risk is the same as Risk N2 and referenced more fully in that section, including relationships to international agreements. Established risk assessment procedure for pests, pathogens, and INNS, covering both existing and new risks, include climate as a key factor. Adaptation policies for each UK country provide continued support for these procedures and biosecurity measures but cannot be regarded as fully robust because they do not define any additional measures based upon the changing risk from climate change, especially if the world were to follow a higher climate change trajectory, such as in a 4°C world. This is of particular concern for new emergent risks that may challenge existing protocols.

The UK Plant Health Risk Register records and rates risks to UK crops, trees, gardens, and ecosystems from plant pests and pathogens, including risk mitigation and new actions to manage or reduce risk. Forest Research maintains a comprehensive and regularly updated compendium of known risks from pests and pathogens to UK forestry, which also includes some information on climate suitability.

Recent enactment of EU Plant Health Regulations into national domestic law in each of the UK administrations has imposed tighter controls on the import and movement of plants and plant materials. However, Post EU-Exit trade agreements are uncertain and could increase the risks of pest/pathogen spread if the controls are relaxed.

The UK has agreed to meet international commitments to control INNS through the Bern Convention and CBD. The Aichi Targets, which fall under the CBD, included a commitment that by 2020 INNS and their pathways would be identified and prioritised, with priority species controlled or eradicated, and pathways managed to prevent species' introduction and establishment. However, in 2019 the UK Government has admitted that progress on meeting this target was "insufficient". As detailed for Risk N7, the GB Non-Native Species Secretariat (GBNNSS) coordinate assessment of INNS across England, Wales and Scotland, whilst Northern Ireland works on a whole-island basis with the Republic of Ireland in an All-Ireland Forum. Risk assessments are a key component of strategic planning and regulation, and if necessary, for legislation to reduce the risk of entry. The Invasive Alien Species (Enforcement and Permitting) Order 2019 introduces enforcement provisions, offences and penalties needed to comply with the requirements of the EU Invasive Alien Species Regulation and gives agencies, police and border force officials new powers to address Invasive Alien Species issues in England and Wales at an early stage. Similar legislation is planned for Scotland.

As identified in previous CCRAs and by the CCC, the current definition of INNS is based upon transfer beyond their native regions by human agency rather than when migration is assisted by a changing climate. This discrepancy is likely to have increasing ramifications for definition of, and actions against, INNS as they become increasingly assisted in their movements by a changing climate.

#### 3.9.2.1.2 England

The forestry sector has developed well-planned actions linked to specific threats as represented by the Defra (2018c) Tree Health Resilience Strategy. The forestry sector's 'Action Plan for Climate Change Adaptation of forests, woods and trees in England' sets out how the sector will enhance protection against the threat of pests and diseases within the context of climate change for the following 5 years. However, at present the 25 Year Environment Plan (25YEP) and second National Adaptation Programme (NAP2) do not outline a measurable goal for managing and reducing the impact of existing plant and animal diseases including for forestry.

#### 3.9.2.1.3 Northern Ireland

The importance of enhanced biosecurity has also been recognised here, including the role of the Plant Health Risk Register (led by DAERA) but again emphasis remains on support for existing measures. Progress from the first Invasive Species strategy (2013) for Northern Ireland was assessed in 2017 and it was concluded that the majority of targets within the 30 key actions had been achieved and steady progress was being made towards non-time limited targets. In 2018 the Invasive Alien Species implementation plan was revised but again explicit reference to climate change risks is rather limited. A recent catalogue of 'Pests and Pathogens of Trees on the Island of

Ireland' now provides a good reference source. There are also plans for further integration of Northern Ireland into a UK Non-native Species Secretariat.

#### 3.9.2.1.4 Scotland

The SCCAP2 highlights the importance of increased biosecurity specifically for forestry pests and pathogens, which links with the scope of the Scotland's Forestry Strategy, although more detailed adaptation actions that go beyond existing initiatives remain to be developed. The SCCAP2 also notes a new potential indicator for the future to record absence of INNS as a complement to the current indicator on presence of INNS.

#### 3.9.2.1.5 Wales

In Wales, adaptation plans also provide ongoing support for existing measures to address INNS and other nuisance species, including improved awareness through the Invasive Non-Native Species (INNS) Portal. Enhanced woodland diversification, as a measure to enhance resilience against increased future threats, is also supported by 'Woodland for Wales' (2018) – the national strategy for woodlands and trees. NRW's Area Statements give opportunities to address INNS in forestry and woodland and the 2nd Wales State of Natural Resources Report has identified four areas of focus for actions by helping to 'improve resilience, including to future climate change and pests and diseases'.

#### 3.9.2.2 Effects of non-Government adaptation (N8)

For the larger forestry stakeholders, much of the focus at present is on disease resistance (e.g., through genetic variation) and stand management to facilitate effective control if an outbreak is detected.

Land managers and others in the supply chain have an obligation to report incidences of specific threats and therefore are a key component of the surveillance system. However, pressures to improve production or trade through nurseries may sometimes lead inadvertently towards increased risk, for example by trialling new species or practices that may be especially associated with particular pests or pathogens (Potter and Urquhart, 2017).

An example of the challenges inherent in managing risks from a complex and dynamic pathogen is provided by the spread of *P. ramorum* which involved a large and diverse range of institutional, industry and private stakeholders (including forestry, horticultural and private garden interests), meaning it was challenging to formulate a coherent response (Potter and Urquhart, 2017). In this case, the complexity of the disease and the diverse range of interests cut across conventional administrative divides between plant health (Defra/Fera) and tree health (FC) responsibilities. However, the lessons learned were then employed to good effect in terms of developing a more proactive and joined-up response to the risk from ash dieback in more recent years. A key part of this response is a recognition of the need for more partnership working; stakeholders commenting on the CCRA have noted that the GB and Northern Ireland Tree Health Advisory Group should have an important co-ordinating role in this context but this has not met in recent years, further

emphasising the need to encourage more partnerships approaches. In addition, co-ordinated activities (e.g., official listing) to recognise more resistant varieties are underway which can further enhance adaptive capacity.

Information campaigns such as Keep It Clean (or Check, Clean and Dry in a more aquatic context – see Risk N12) have been successful at increasing broad awareness of the threats and the need to adopt good practice. In terms of stakeholder awareness, the British Woodland Survey in 2020 (BWS2020: Hemery *et al.*, 2020) showed there was strong awareness of environmental changes observed in woodlands in the last five years and that perceptions were that this risk was increasing, particularly for *Pathogen damage* (79% observing increase since 2015) and *Vertebrate pest damage* (55% observing increase since 2015). Pests and pathogens were considered the main factors influencing a change in management, with 66% of woodland owners in the 2020 survey considering diversifying tree species as a response. However, it should also be noted that forest surveys have shown that a significant proportion of the UK woodland stock is not ‘actively managed’ which may impede detection and control. BWS2020 found that most respondent woodland owners (69%) did not have a UKFS compliant management plan in place.

The Wales Invasive Non-Native Species Group includes many non-governmental organisations as members and has provided productive support towards tackling INNS in Wales. This includes work undertaken by local action groups and the Wales Resilient Ecological Network (WaREN).

### 3.9.2.3 Barriers preventing adaptation (N8)

As highlighted above for *P. ramorum*, new threats sometimes cut across conventional institutional responsibilities and require new ways of working and co-ordinated initiatives. Similarly, with the threat from oak processionary moth, it was originally not clear whether the primary responsibility was as a plant health issue or a public health issue, meaning there were delays whilst it was determined who should lead the response. In addition, adaptation requires up-to-date information on the threat of establishment or spread to further encourage active surveillance, and complacency may be a concern in areas not previously exposed. It also requires co-operation beyond national boundaries which may be variable. Investigation of disease suppression has shown the importance of early detection and movement controls.

Surveillance and control actions typically occur on a sectoral basis (or even a sub-sectoral basis for specialist sectors such as horticulture), so actions are not always co-ordinated, and knowledge of changing risks can be variable. Past incidents have shown that assumed priorities to maintain or increase production can mean that excessive risks (e.g., regarding material of unknown provenance) may be taken (Potter and Urquhart, 2017). It has also been suggested by some stakeholders commenting on the CCRA that there may be additional pressures to relax regulations in order to enhance trade following EU-exit, or to improve productivity via new species, which could also exacerbate risks, highlighting the need to better communicate costs and benefits of biosecurity measures throughout the sector including to the public (Eriksson *et al.*, 2019).

### 3.9.2.4 Adaptation shortfall (N8)

Existing institutional risk assessment procedures provide some adaptive capacity that will help to reduce the residual risk to a lower level than it would otherwise be given the increasing risks from climate change, and this will have continuing benefits in reducing residual risks in the future. However, future climate change, especially in a world with a higher magnitude of climate change, will almost certainly bring new risks that challenge current procedures. In particular, as with the other risks in this chapter considering pests, diseases and particularly for INNS, what is missing is explicit recognition of the changing risk from climate change in the policies mentioned above, including scenarios up to a 4°C world. Risk management strategies therefore require further extension to better recognise emergent risks rather than just the 'known knowns' and also to develop a stronger long-term adaptation perspective based upon multiple future scenarios. Hence the anticipated threat is only partially addressed and there is a future adaptation shortfall. Confidence is low because of the limited evidence on the efficacy of adaptation measures and because of the complex interaction of climate risks with socio-economic factors.

### 3.9.2.5 Adaptation Scores (N8)

<b>Table 3.27. Adaptation scores risks to forestry from pests, pathogens, and INNS</b>			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.9.3 Benefits of further adaptation action in the next five years (N8)

As with risks N2 and N7, with which there are many commonalities, the need for cross-sectoral co-ordination and surveillance requires more action and research especially focussed on the following issues:

- Surveillance and modelling for emerging risks.
- Further modelling of risk reduction measures for pests, pathogens and INNS.
- Further assessment of climate factors in risk assessment that would be beneficial in early warning.
- Understanding current and future risk from non-native species vectors and pathogens.
- Improved biosecurity, especially at ports of entry.
- Changes to plant purchasing and sourcing practices to highlight importance of secure sources and provenance (e.g., certification).
- Increased emphasis on disease and pest resilience.
- Further investigation of management initiatives to enhance resilience, such as diversification (see adaptation options investigated for forestry in Risk N6).
- Improved understanding of current and future risk from non-native tree species used, or proposed, for enhanced production purposes.

The role of genetics may have an important role in developing improved resilience to pests and pathogens (Telford *et al.*, 2015; Fady *et al.*, 2016). This may include changes to the chosen provenance of tree planting stock (e.g., seed sourcing) based upon known resistant varieties and improved knowledge exchange with land managers on this topic, especially where the goals for forestry are multifunctional and not just related to production (Whittet *et al.*, 2019).

### 3.9.3.1 Indicative costs and benefits of additional adaptation (N8)

The economic case for further uptake of existing adaptation measures is sound, as evidenced by the discussion above: it is much more effective to prevent introduction and establishment rather than attempt to mitigate spread and resulting impacts. Watkiss *et al.* (2019) explored the possible costs and benefits of adaptation for a number of forest pests and pathogens (once established). The analysis indicated that it is possible to manage changing pathogen risks, at least to some extent, using existing adaptation options. However, there are large resource costs associated. There are therefore benefits from further adaptation that avoids these risks. This includes a key role for public co-ordination of monitoring and surveillance.

Previous analysis by SRUC (2013) has identified that investment in monitoring for pests has a high benefit-cost ratio of around 10:1. There are also clear benefits from Government investing in information about pests and pathogens – their spread, likely impacts, and treatment methods – as this information flow would not otherwise occur. Whilst a large proportion of the costs (for pests and pathogens) may be borne by private land-owners, public support is likely to be needed where there are local concentrations of economic activity that are threatened by the rapid spread of one of these pathogens in an area (to reduce the much larger costs once pests and pathogens become established, i.e., management plans and emergency response). This economic argument is strengthened by climate change, because the future nature of the threats will be less understood by private actors' past experience.

Cost-benefit analysis of enhanced measures to address INNS are also discussed in Risk N7.

### 3.9.3.2 Overall urgency scores (N8)

<b>Table 3.28 Urgency scores for risks to forestry from pests, pathogens, and INNS</b>				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Quality of evidence</b>	Medium	Medium	Medium	Medium

A 'More Action Needed' score based on medium quality of evidence has been assigned to this risk. The high projected magnitude for this risk in future (which would be very likely to become even more pronounced under higher scenarios of climate change) and the severe challenges presented to

existing procedures (increase in risk species and micro-organisms, including emergent threats) indicate the need for further measures to to reduce risk.

Improved surveillance is required, especially in the context of the need for improved international co-ordination following EU-exit and associated trade agreements. It is also suggested to continue current research efforts into the impact of climate change on long-term risks. Cross-sectoral initiatives for risk assessment and contingency planning should include the following:

- Further development of international monitoring initiatives, surveillance, risk assessment procedures and bio-security measures based upon UKCP18 and other relevant climate change data.
- Enhanced horizon scanning for INNS from Europe and based upon a changing international trade portfolio. Cross-sectoral initiatives for risk assessment and contingency planning using a range of diverse scenarios (including with agriculture, horticulture, and biodiversity sectors).

#### 3.9.4 Looking ahead (N8)

Improved spatial and temporal profiling of specific risks including for years with particularly extreme weather would help to better understand changing risk factors in combination with changing socioeconomic factors (e.g., trade patterns).

### 3.10. Opportunities for agricultural and forestry productivity from new/alternative species becoming suitable (N9)

- Future climate change, especially warming, will enhance climate suitability for new crops. However, there is limited evidence available to assess the magnitude of potential opportunities.
- In agriculture and horticulture, a wide range of potential opportunities may be identified, some of which are already being developed as niche crops in suitable areas.
- In forestry, trees that are cold-limited and presently restricted to lowland areas and southern England will be suitable for growing in increasing areas in a warming climate.
- Based on limited evidence, the assessment concludes the level of opportunity will increase from medium at present to potentially high in the future.
- Inertia in land use decision-making at multiple levels of society means much of the adaptation opportunity for agricultural and forestry productivity remains unrealised.
- This topic has been assessed as a priority for 'Further Investigation' in conjunction with ongoing policy initiatives to advance the innovation economy in the UK.
- Changes in trade and regulatory agreements following the UK's departure from the EU will have important implications for this topic.
- Realisation of opportunities will also require that associated risks to the agriculture and forestry sectors (N6, N7, N8) and to soil health (N4) are also effectively managed.

## Introduction

We have defined this opportunity-related topic in the broader sense to include climate-related developments that can occur through new species, varieties, and cultivars, together with any new cropping combinations (either as mono- or inter-crop combinations). It also includes the potential for movement of existing species (or varieties/cultivars) in one UK country or region into another country/region, thereby presenting novel opportunities in that new location. In each of these cases, agricultural or forest productivity may be enhanced. As previously discussed for Risk N6, sustainable productivity issues are a key challenge for the natural environment, and of high relevance not only to land managers and rural communities but also the population as a whole due to the implications for domestic supply of food and other commodities.

The level of opportunity is assessed to increase from medium (present) to possibly high in future, although evidence is rather limited. Much of this opportunity remains unrealised in terms of adaptation. This is probably due to inertia in decision-making at multiple levels of society from land managers to institutions and policy: for example, inertia is exemplified by a focus on climate change 'resilience' being interpreted as maintenance or enhancement of current production systems. Therefore, this topic is recommended as a priority for 'Further Investigation' in conjunction with ongoing policy initiatives to advance the innovation economy in the UK.

As with Risk N6, it is very likely that EU-exit will have important implications for this topic, but this will be very dependent on how it changes trade and regulatory agreements. COVID-19 may also have important implications but at present there is very little evidence on these wider interactions.

### 3.10.1 Current and future level of opportunity (N9)

#### 3.10.1.1 Current opportunity (N9)

There is presently limited information on the establishment and spread of new crops and other exotic produce, especially in a spatial context. Prominent examples that have featured in news item-type reports include chickpeas, quinoa, vines, soya, and lentils. Other crops known to have been grown recently in the UK include peaches, apricots, tea, sunflowers, sweet potatoes, watermelons and walnuts, whereas exotic produce has recently extended to include truffles (Thomas and Buntgen, 2018). However, some of these crops are grown in sample trials developed within the ethos of agricultural/horticultural entrepreneurship rather than being developments that have led to actual commercial-scale production opportunities. In some cases (e.g., apricots), new opportunities are associated with hardy new cultivars that appear to be more adapted to the variable UK climate, especially the continuing risk of occasional frosts.

The area under vines in the UK has increased by 160% in the past 10 years and is currently around 2500 ha. About 700 vineyards exist (of which about 75-80% are commercial), and over 160 wineries (WineGB, 2018). In 2018, 1.6 million vines were planted with a further 2 million planned for 2019 (but not confirmed). The variability of the UK climate involves challenges for production with inevitable 'good' and 'bad' years. The hot dry summer of 2018 meant that a record 15.6 million bottles of wine were produced (the previous record was 6.3 million bottles in 2014) (ADAS, 2019). Some other recent years have been poor for production, notably 2012 which featured a very wet

cloudy summer in the wine-growing areas. Analysis of current vineyard locations using a Viniculture Suitability model based upon bioclimate, soil, topography and other data has shown that they are rather sub-optimally located when compared to the most favourable sites from a biophysical perspective (Nesbitt *et al.*, 2018), emphasising again the underlying socioeconomic factors that influence land use decisions (see Risk N6). Nevertheless, in a warming climate, enhanced suitability for viniculture and wine production presents an important business opportunity to move away from traditional crops (see also Chapter 6: Surminski, 2021).

An expanding crop in the UK is soya, with the area increasing from 8 ha to 500 ha between 2012 and 2017, as warmer temperatures are providing a larger area of the UK suitable for production. Triticale (a wheat/rye hybrid) is another crop with significant opportunities that has actually been present in the UK for a long time, but with limited uptake (less than 0.2% of current cereal production). Most commonly, it has been a second arable rotation crop following wheat due to its better resistance to root take-all disease. Triticale is mainly used for forage, but can be used in cereal food products, bioethanol, and anaerobic digesters. Compared to wheat, yields of triticale seem quite robust both to cooler wetter summers (e.g., 2012) and to drought conditions, despite slightly higher lodging risk (Bassu *et al.*, 2011; Roques *et al.*, 2017). Triticale has a more developed rooting system than wheat which means it can be more effective in capturing soil nutrients, hence requiring less fertiliser, with reduced soil N losses to air and water (and P losses to water). The resulting reduced N<sub>2</sub>O emissions mean it has been identified as a good candidate for climate mitigation policies linked to Net Zero GHGs, with indicative emission reduction factors scoped by CCC (2020) but also further assessment required. The extensive roots have good soil binding potential, especially with lighter soils, which can reduce erosion risk, and it can also enhance organic matter and improve soil structure with good management practice. However, it is not yet fully known how the changing suitability for triticale cropping, and its relative advantages compared to wheat, will vary with future climate change projections, although existing information indicates it may be more resilient to extreme events.

Potential production opportunities already also exist through intercropping, both as whole crop silage and harvest for grain, although uptake is limited at present. Intercropping uses complementary plant relationships (species mixtures such as cereal/legume; or cultivar mixtures) to enhance productivity or reduce inputs, and there is increasing interest in using such approaches for climate adaptation with large-scale meta-analysis showing potential for greater yield stability from cereal-grain legume intercropping (Raseduzzaman and Jensen, 2017). At a field trial site in eastern Scotland, Newton *et al.* (2019) evaluated cultivar mixtures of winter barley and spring barley during 2015-16 compared to equivalent monocultures and found overall grain yields significantly higher for the cultivar mixtures and also that these mixtures decreased rhynchosporium disease for most non-fungicide treatments. Evidence was less conclusive regarding straw yield, which may be more sensitive to interannual climate variability.

Forestry has a more co-ordinated programme for trialling new species, including evaluation of the most suited provenances to allow trees to adapt to UK conditions. Forestry Commission (FC) data indicate that ca. 25% of trees planted in FC forests are currently less traditional species. This includes species that are fast growing and therefore provide opportunities for enhanced productivity but may also present additional risks, such as from wildfire (e.g., eucalyptus). Climate warming is also

allowing expansion in the use of some established productive species into new areas (e.g., Douglas fir).

An important driver for pioneering new crops and varieties is the Net Zero GHG agenda, through which production gains are associated with reduced GHG emissions, either through direct effects on emissions pathways or indirectly by sparing land for alternative land uses as carbon sinks (notably forestry). In addition to new cultivars such as crops bred for enhanced N-use efficiency crops, this may also include further expansion of existing crops such as triticale. Another noteworthy example, which may be especially relevant for the wetter areas of the UK where livestock farming dominates is the development of High Sugar Grasses (HSGs) that can provide more forage energy and therefore protein, which in turn can increase livestock meat and milk production, while reducing N losses to air and water (Parsons *et al.*, 2011; Soteriades *et al.*, 2018).

### 3.10.1.2 Future opportunity (N9)

Future climate change, especially warming, will enhance climate suitability for new crops but, by comparison with research on changing suitability for existing conventional crops, there is limited evidence currently available to assess the magnitude of potential opportunities. Notable exceptions include previous analysis of changing suitability for bioenergy crops in a warming climate in the UK which identifies opportunities for expansion of some crops into new areas (e.g., Bellarby *et al.*, 2010), and recently-derived suitability analysis of a wide range of crops in Wales based upon UKCP18 data and bioclimate metrics (Bell *et al.*, 2019). The latter included novel crops (e.g., tea and almond) in addition to existing crops and indicated potential for expansion in some cases. However, it should also be noted that some of these novel crops typically have a high water requirement to sustain growth and this reduces their suitability, including in existing areas. The suitability analysis in Wales identifies drought risk as a key constraint that increases in future and as discussed in Risk N6 this would be an even more significant factor in some areas of eastern England. Nevertheless, for crops that are adapted to limited water availability this may provide new opportunities. It should also be noted that existing work on changing crop suitability does not consider advances in crop genetics, under-cover cultivation, hydroponics, aeroponics or other technologies, or availability of supplemental irrigation. In addition, local variations in the capability of the land may also be crucial, as occurs with topography, aspect and microclimate (e.g., south-facing versus north-facing slopes) and different soil types (e.g., water-intensive bioenergy crops may be suited to alluvial soils on fluvial floodplains but less suited for more marginal soils, such as thinner soils on valley sides). Suitability analysis will also require to be further refined to include changes in productivity that occur due to elevated atmospheric CO<sub>2</sub> levels (and related feedback issues such as water requirements and water-use efficiency).

Analysis of opportunities from viticulture generally report positive outcomes in a future climate, although often do not consider the full suite of variables that may affect wine production. For example, in a scenario reaching approximately 3°C global warming at the end of the century<sup>20</sup>, large areas of the UK (excluding the wetter western regions) may be suitable for viticulture in 2100, mostly for white grape varieties and Pinot Noir, although not in this scenario for warm climate grape

---

<sup>20</sup> Unspecified climate model driven by the RCP6.0 concentrations pathway

varieties such as Sangiovese, Cabernet Sauvignon and Grenache/Garnacha. (Georgeson and Maslin, 2017). The same indicative analysis also inferred to an increasing risk that current wine-producing areas in the south of England may become less suitable for some of the cool climate grape varieties, such as Pinot Noir, but may have the potential for intermediate climate red wine grapes (e.g., Merlot and Tempranillo) in favourable locations such as Kent, Essex, Norfolk and Cambridgeshire. Climate change could therefore open a range of opportunities for growing different varieties of grapes, depending on future magnitudes of warming but also changing seasonal rainfall patterns (heavy autumn rainfall can be particularly detrimental). Viniculture is also affected by temperature variability and extremes, notably from the frequency and intensity of mid-winter low temperature, late spring frosts, and the influence of excessive summer heat (Nesbitt *et al.*, 2016). An analysis of the opportunities for wine in the UK was undertaken as part of the CCC outcomes project (Watkiss *et al.*, 2019), based on the literature and wine sector ambitions. This estimated that if a 10% increase in production was realised by the 2050s (based on long-term wine sector goals), this would translate to additional revenues of approximately £22-80 million/year. A higher estimate, based on a 25% increase, could lead to additional benefits in the range of £54-200 million/year. These figures are based upon multi-year averages, but high annual production variability is also noted, and an increase in interannual climate variability would be likely to have negative implications with significant contrasts between good and bad years, as occurs at present. An additional factor will be climate change impacts on wine growing areas in other countries, which if negative (as some studies suggest) could create increased export opportunities for the UK.

For forestry, trees that are cold-limited and presently restricted to lowland areas and southern England (both native and non-native species) will be suitable for growing in increasing areas in a warming climate (Forestry Commission, 2020b). This includes productive species, such as eucalyptus, radiata pine (although potentially vulnerable to *Dothistroma* needle blight), red fir, and silver fir, together with productive broadleaf species such as lime, false acacia, London plane, field maple, and aspen, and those species which are valued for other distinctive properties (e.g., in woodcraft; amenity value; fruits and nut production) such as sweet chestnut, hornbeam, cherry, and walnut, especially if natural regeneration is facilitated. Further opportunities for expansion of existing established species such as Douglas fir and sycamore are also very likely to occur and fast-growing species that are selected for bioenergy sources (e.g., black poplar) will also benefit from warming. Emphasis will also need to be placed on tree species selection matched to the right soil type and other conditions such as soil moisture, and exposure. Notably, the projected reduction in summer soil moisture for eastern England and increased frequency of drought conditions may exclude sensitive species from these locations. In addition, some species may become more vulnerable to pests and diseases (Risk N8). For some species (e.g., poplar), climate warming may also allow the use of clones that are currently not hardy in Britain.

Another land use option with potential new opportunities is agroforestry. Although agroforestry systems have existed in the UK for centuries, present use is very much diminished (see Risk N6). However, the changing climate offers scope for new combinations, either for trees with pasture or arable, and this is another future option that deserves further investigation, especially in the contexts of multiple benefits and not only for production objectives.

#### 3.10.1.3 Lock-in (N9)

Inertia in the agriculture and forestry sector may prevent the transition to more productive and efficient crops (efficiency here being defined as maximised outputs per unit of input whilst also reducing negative externalities). For some crops, lock-in could be a risk. Watkiss *et al.* (2019) highlighted that the expansion of cultivated area for wine (new planting) involves long lifetimes and considerable lock-in, because it requires land-use change and high capital investment. The payback period on wine is longer than for many other agricultural crops, and this means that early decisions on new expansion areas in the short- and medium-term need to be evaluated against the future climate in the medium-term and even in the longer-term.

#### 3.10.1.4 Thresholds (N9)

As identified by CCRA2 and discussed further for Risk N6, there are important bioclimate thresholds related to species requirements, especially temperature and moisture thresholds, which can be characterised through the changing patterns of UK land suitability for each species. The analysis of changing crop suitability in Wales referred to above (Bell *et al.*, 2019) has used this mode of analysis to define different levels of suitability based upon multiple bioclimate variables for each selected crop.

#### 3.10.1.5 Cross-cutting risks and inter-dependencies (N9)

There are known and unknown risks from pests, pathogens and INNS which may impact on productivity (Risks N7 and N8). Pests, pathogens, or INNS may present particularly damaging challenges for newly introduced crops or varieties, as their natural enemies/competitors may not be present in the UK; in addition, they may have detrimental impacts on pollinators, which are an essential requirement for the production of some crops (Vanbergen *et al.*, 2018). Newly introduced crops or trees may have a negative impact on biodiversity because they offer less support for native invertebrates; this may then affect other trophic levels that rely on invertebrates. In addition, for some crops there will be important interactions (positive and negative) with soil, air and water quality. More specifically, fast-growing crops (including tree species used for short-rotation coppice or short-rotation forestry) that may be prioritised for production purposes also tend to have high water requirements, and in some cases novel species (e.g., eucalyptus) can have a high fire risk as has been found from large-scale planting in other countries (Mirra *et al.*, 2017; Nolan *et al.*, 2018; Belcher *et al.*, 2021). The role of new crops within arable rotations may be especially important in delivering co-benefits in addition to production objectives. Evidence for most of these cross-cutting risks and their interaction with opportunities in agriculture and forestry due to climate change is very limited in the UK but potentially available from other countries, although the land-use context may be different.

#### 3.10.1.6 Implications for Net Zero (N9)

As noted above, there are important interactions with the Net Zero GHG agenda in terms of potentially reduced emissions, and some new crops may provide additional health and nutritional

benefits that enhances efficiency of food supply per unit of equivalent carbon emissions. Further work using life-cycle analysis would be beneficial to confirm these putative gains. Analysis of energy crops (SRC, miscanthus etc.) suggests there may be a useful co-benefit for potential flood alleviation if planting occurs to replace arable crops on floodplains due to their additional hydraulic effects in slowing river flow (Rose and Rosolova, 2015).

### 3.10.1.7 Inequalities (N9)

As discussed for Risk N6, availability of good quality, nutritious, food is also an important human health issue and in negative terms can be associated with issues of 'food poverty' that can especially affect more vulnerable people in society. Opportunities for new produce through novel species or varieties, can potentially have an important role in addressing these societal challenges, particularly when linked with local food initiatives that enhance the supply of fruit, vegetables, and other staple foods.

However, no specific evidence showing how inequalities may be modified through this climate change opportunity has presently been identified.

### 3.10.1.8 Magnitude scores (N9)

**Table 3.29** Magnitude scores for opportunities for agricultural and forestry productivity from new/alternative species becoming suitable.

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
England	Medium	Medium-High	High	High	High
	(Low confidence)	(low confidence)	(low confidence)	(Low confidence)	(Low confidence)
Northern Ireland	Medium	Medium-High	High	High	High
	(Low confidence)	(low confidence)	(low confidence)	(Low confidence)	(Low confidence)
Scotland	Medium	Medium-High	High	High	High
	(Low confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
Wales	Medium	Medium-High	High	High	High
	(Low confidence)	(low confidence)	(Low confidence)	(Low confidence)	(Low confidence)

Notes: Magnitude categories are based on expert judgement of existing/expected impacts on production outputs due to the limited available quantitative data for this topic. As many crop types and tree species have a clear climate sensitivity which influences when and where they can be cultivated, we have projected that the potential opportunity increases from medium (present) to high under most future climate projections, although it may not increase by quite as much by 2050 on the lowest trajectory of future climate change. Confidence is low for all of this assessment due to the limited information available, especially when extrapolating to a national scale.

### 3.10.2 Extent to which current adaptation will manage the opportunity (N9)

#### 3.10.2.1 Effects of current adaptation policy and commitments on current and future risks (N9)

Existing national policy frameworks that have relevant commitments for adopting new species in agriculture and forestry production are discussed in Risk N6. As highlighted there, much of the emphasis across all UK nations is on 'climate resilience', interpreted in terms of enhanced production from current systems. Current policy support throughout the UK is therefore limited with regard to new opportunities for new species, although some is provided through associated funding for long-term crop trials and new evidence-support initiatives such as the changing crop suitability analysis for the Capability, Suitability and Climate Programme in Wales (Barrow et al, 2019, referred to above). These initiatives are providing an initial step in highlighting spatial variations in the availability of new opportunities. We have been unable to find specific examples of other government initiatives that focus on supporting the uptake of new species in agriculture or forestry in the context of climate change adaptation.

This topic therefore currently appears to be seen predominantly as an industry-led issue linked to market opportunities. With commitments for Net Zero GHG emissions and national Food & Drink strategies promoting a shift towards more local/national production and healthy diets, this lack of government support may be seen as an important adaptation gap if the market involves barriers to uptake. In response, initiatives that allow policy to become more of an enabler and to support entrepreneurship regarding new opportunities can be identified as a valuable mechanism to enhance adaptive capacity. For example, this may include the use of grants (analogous to support for new technology), support for specialist knowledge exchange networks, and an increased role for an innovation-related organisation to act as a champion and lead coordinator between research and industry.

While the private sector would be expected to take advantage of opportunities, there may be an important role for Government in order to fully realise these benefits. An example has been given for the wine industry (Watkiss *et al.*, 2019), which found there was a potential role for Government to provide the enabling environment to take advantage of the positive changes in suitability and productivity being seen in the UK. This includes the provision of information (including for future wine suitability) which is particularly important given the lock-in involved with the expansion of wine production areas (i.e., for wine investment decisions in the next decade due to the long-life time and high capital investment costs for vines).

### 3.10.2.2 Effects of non-Government adaptation (N9)

In agriculture, opportunities are being investigated by industry and individual farmers, but research is often limited compared to the scale of investment in conventional species/varieties. Typically, the level of investment in new crops or cropping systems is linked to perceptions of market opportunities and the level of risk incurred by that investment relative to future economic returns. Adoption and spatial diffusion of new crops, including the contingent interaction of supply and demand, typically takes rather longer than anticipated with time lags for the UK between early and full adoption of about 20 years based upon both empirical analysis and simulations (Alexander *et al.*, 2013). For example, investment in triticale is extremely small compared to the large-scale research programmes developed for wheat, although information is gradually being collated on its relative advantages and market opportunities, including a recent AHDB and Innovate UK funded project (Clark *et al.*, 2016). More generally, AHDB provide advice and guidance for some species and especially on new cultivars. However, to better anticipate and realise some of the new opportunities provided by climate change, more knowledge exchange, co-ordination of initiatives, and outreach activities such as demonstration projects to build adaptive capacity is required.

The forestry sector has a more established programme of trialling opportunities from new species. For example, the 'Silvifuture' network ([silvifuture.org.uk](http://silvifuture.org.uk)) has been established to promote and share knowledge about novel forest species across Britain.

A very interesting example of the development of local-scale opportunities is the introduction and cultivation of non-traditional crops by particular ethnic groups at community level, including as allotment-holders, and in some cases subsequently being grown on a commercial scale. A recent survey and inventory of exotic crops grown on allotments (e.g., white maize, callaloo, dudi (bottle gourd), okra, chayote, and honeyberry), including by whom and why they are grown, provides a very useful baseline (Kell *et al.*, 2018). The majority of smallholders save their own seed, indicating crops are performing well in the UK and that this diversity is being maintained over the longer term, whilst also swapping seed with other growers, which further enhances diversity in response to different growing conditions, including climate conditions well beyond their normal range. A study of European commercial plant nurseries showed that 73% of garden species were able to survive an average of 1000km further north than their known natural range limits usually through a modified microclimate (greenhouses, walled gardens, polytunnels, hotbeds etc.) (Van der Veken *et al.*, 2008).

### 3.10.2.3 Barriers preventing adaptation (N9)

There is presently limited information on new opportunities targeted at breeders and growers. For example, AHDB provide lists of recommended crops and cultivars and these could be expanded to include a measure of durability to climate. In addition, the breeding profile and trials could have an improved evaluation of climate information, including variability and extremes (Falloon *et al.*, 2018), to allow more informed decisions on the balance between risk/opportunity regarding crop/cultivar choice.

Another practical barrier is the refinements in processing technology (food, fibre or energy) that may be required to enable opportunities to be realised. For example, the harder texture and larger

grain size of triticale are currently associated with lower milling yield compared to wheat (Dennett and Trethowan, 2013). A large-scale shift to more efficient use of triticale in flour production would require refinements to current milling technology which are currently specified based upon the requirements for wheat. Similarly, there have been concerns that use of miscanthus in bioenergy production using a conventional sodium hydroxide or sulphuric acid pre-treatment can have negative side-effects due to acidification, soil toxicity, and eutrophication impacts from residues unless processing plant is further modified (or, potentially, hot water pre-treatment is used instead) (Lask *et al.*, 2019).

These concerns identify a deeper underlying issue which relate to the difficulties in new opportunities being realised when in competition with existing uses. For example, commercial development and planting of new crops/cultivars is often dependent on other locational issues such as the availability of processing plant and related demand from the food, drink or energy sector. This may require significant capital investment and the development of centralised resources to facilitate these synergies, but this is typically beyond a small-scale grower and requires either the involvement of larger businesses, increased business co-operation, or an increased role for policy in stimulating local or regional opportunities, these issues are further discussed in Chapter 6. Similarly, in the forestry sector, although an interest in growing more exotic species has been noted, the availability of markets for these species has acted as a significant barrier (Lawrence and Marzano, 2014). Stakeholder analysis in the Scottish forestry sector has also highlighted that species choice is a social as well as an economic and technical choice, because different people involved in land use have different objectives and preferences (Lawrence, 2020).

There is therefore a potential role for Government to support early actions to address existing information and other barriers and create an enabling environment for the private sector. However, for political reasons, some government departments are not keen to be openly promoting increased uptake of opportunities as this might be seen as welcoming climate change.

#### 3.10.2.4 Adaptation shortfall (N9)

Our interpretation of the limited evidence for this topic is that much of the adaptation opportunity for agricultural and forestry productivity remains unrealised due in large part to inertia in decision-making at multiple level of society. At present, the topic appears to be seen as predominantly an industry-led issue linked to market opportunities; however, there is likely to be an important role for Government in order to fully realise these benefits by providing support and information, and by removing other barriers to greater uptake (see below).

At present therefore, it is our assessment that most of this benefit will not be realised in the absence of additional government intervention. This should be a major source of concern because the opportunities identified here could provide the potential for increased domestic and local food supply, reducing the reliance on imported food. With future population projections showing a continued increase in the UK population over coming decades (around 10 million more people by 2050 under a central projection), even if the same balance between domestic and overseas food supply is assumed (e.g., as in the CCC (2020) Net Zero scenarios) then an increased domestic supply

will be required to meet increased demand. As highlighted also for Risk N6, at present it is not clear how this increased demand will be met in a changing climate, notwithstanding other potentially major socioeconomic changes, such as changes in diet or reduced food waste. Confidence in the assessment of current levels of adaptation is low because of the limited evidence.

### 3.10.2.5 Adaptation Scores (N9)

<b>Table 3.30 Opportunities for agricultural and forestry productivity from new/alternative species becoming suitable</b>			
<b>Are the opportunities going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
No (Low confidence)	No (Low confidence)	No (Low confidence)	No (Low confidence)

### 3.10.3 Benefits of further adaptation action in the next five years (N9)

Currently crop breeding mainly focuses on yield and disease resistance and the multiple effects from climate change are not generally systematically considered, meaning there is a need for a more co-ordinated approach that includes both a wide range of potential future crop growth facilitators and stresses (e.g., disease, drought, heat, waterlogging etc.). More detailed scoping and investigation of opportunities is required that is also consistent with changing patterns of land capability and individual crop suitability across the UK. A major gap in knowledge and knowledge exchange appears to exist for opportunities for fruits, vegetables, and horticultural crops in a future climate, which would seem especially important because of the key role of these crops in human nutrition, including local availability and variety. Consumer surveys have suggested there is a significant unrealised demand for local produce, and more emphasis on new opportunities could have a key role in meeting that demand. As noted above, based upon the survey of non-traditional crops grown by smallholders in the Midlands (Kell *et al.*, 2018), there are also important food-cultural interactions with growing diverse local crops that could be further supported. In addition, new opportunities related to inter-cropping and agro-forestry require further systematic investigation in relation to improved understanding of different combinations in a wide variety of contexts, and the existing barriers that prevent increased uptake.

#### 3.10.3.1 Indicative costs and benefits of additional adaptation (N9)

The analysis of the wine sector (Watkiss *et al.*, 2019) found there were early low regret actions that could be introduced to increase the opportunity presented by a warming climate, as well as to reduce the risks associated with possible climate variability (particularly the risks to grape growth from cold snaps). The study also found a large number of no- or low-regret options from Europe for addressing climate variability that could be adopted in the UK (e.g., Neethling *et al.*, 2016). The research also undertook an initial analysis of the potential costs and benefits of additional early adaptation. This indicated that under a scenario where wine growers were able to realise the

benefits of climate change due to better information, and at the same time introduce adaptation measures to address potential variability risks, there would be very large economic benefits. The consideration of similar opportunities is less well characterised, but similar activities should be included for further investigation.

### 3.10.3.2 Overall urgency scores (N9)

<b>Table 3.31</b> Urgency scores for opportunities for agricultural and forestry productivity from new/alternative species becoming suitable				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	Further Investigation	Further Investigation	Further Investigation	Further investigation
<b>Confidence</b>	Low	Low	Low	Low

The primary constraint for adaptation decision-making at present is the limited information available (as consistent with the assigned low quality of evidence), therefore we identify this topic as an urgent priority for further investigation. Nevertheless, our view based on the evidence available is that there is an important role for policy in this investigation process, such as by providing increased support for adaptive innovation through field or stand trials, or new cropping systems, and to enhance knowledge exchange related to such initiatives to encourage greater uptake and collaborative learning.

#### Areas of focus:

- More systematic investigation is required, including a review of barriers to the market taking up the opportunities for new species, outreach activities and collation of existing and new knowledge on species and cultivars, and innovative cropping/silviculture systems.
- There is potential for grant-funding mechanisms in the new funding schemes for land managers that are replacing the Common Agricultural Policy to further support innovation and knowledge sharing related to these new opportunities based upon further trialling of the benefits.

### 3.10.4 Looking ahead (N9)

Particularly useful for this topic would be an inventory of changing distribution of crops/varieties/cultivars as an extension of the Defra and Scottish Government annual production census for agriculture and forestry, including geographic changes in distribution. This could also cover changes in the uptake of inter-cropping systems and other related novel practices. It would also be useful to obtain more information on changing climate suitability and climate resilience from crop breeding programmes, trials, and commercial programmes, such as through a co-ordinated knowledge exchange initiative. Another important source of evidence would be a robust assessment

of the potential for growing a wider range of crops than at present (considering both productivity and land suitability), in support of healthy food systems and also linking with the Net Zero agenda.

### 3.11. Risks to aquifers and agricultural land from saltwater intrusion (N10)

- Future risk to aquifers and agricultural land from seawater saline intrusion is expected to increase gradually with sea level rise and may be more pronounced during drought periods depending on any adjustment to water abstraction rates.
- Current risk at national scale is assessed as low at present and most likely to remain low in future (although potentially higher for England and Wales in a 4°C scenario by the 2080s). However, the scale of intrusion risk would significantly increase should a more extreme rate of sea level rise occur (a High++ scenario).
- No additional intervention is presently needed to manage current and future risk, however, there is limited evidence for this topic and further research on changes in exposure and vulnerability is recommended, especially as risk is more localised in some areas.
- England and Wales are assessed as needing 'Further Investigation', while Scotland and Northern Ireland have been assigned a 'Watching Brief' due to the lesser scale of risk exposure given present available evidence.

#### Introduction

This risk defines the threat that saline intrusion from sea level rise causes for coastal aquifers and agricultural land. A transition to saltwater or brackish water has important implications for availability of water resources and their use to support productive land use, depending on the scale and timing of intrusion. Our assessment of available evidence is that the risk is currently low at present and most likely to remain low in future unless a much greater rate of sea level rise was to occur (a High++ scenario) and therefore the scale of intrusion would significantly increase. Continuing current risk management procedures therefore would seem to remain adequate to adapt to the risk. However, evidence is rather limited for this issue and further research on changes in exposure and vulnerability is recommended, including in the context of the latest scientific data on sea-level rise. For Scotland and Northern Ireland this appears a lesser risk as the scale of exposure appears smaller (although evidence is even more constrained here) and continuation of a 'watching brief' is therefore probably more appropriate.

Links between this risk and either EU-exit or COVID-19 remain to be further established as there is no known evidence on these interactions.

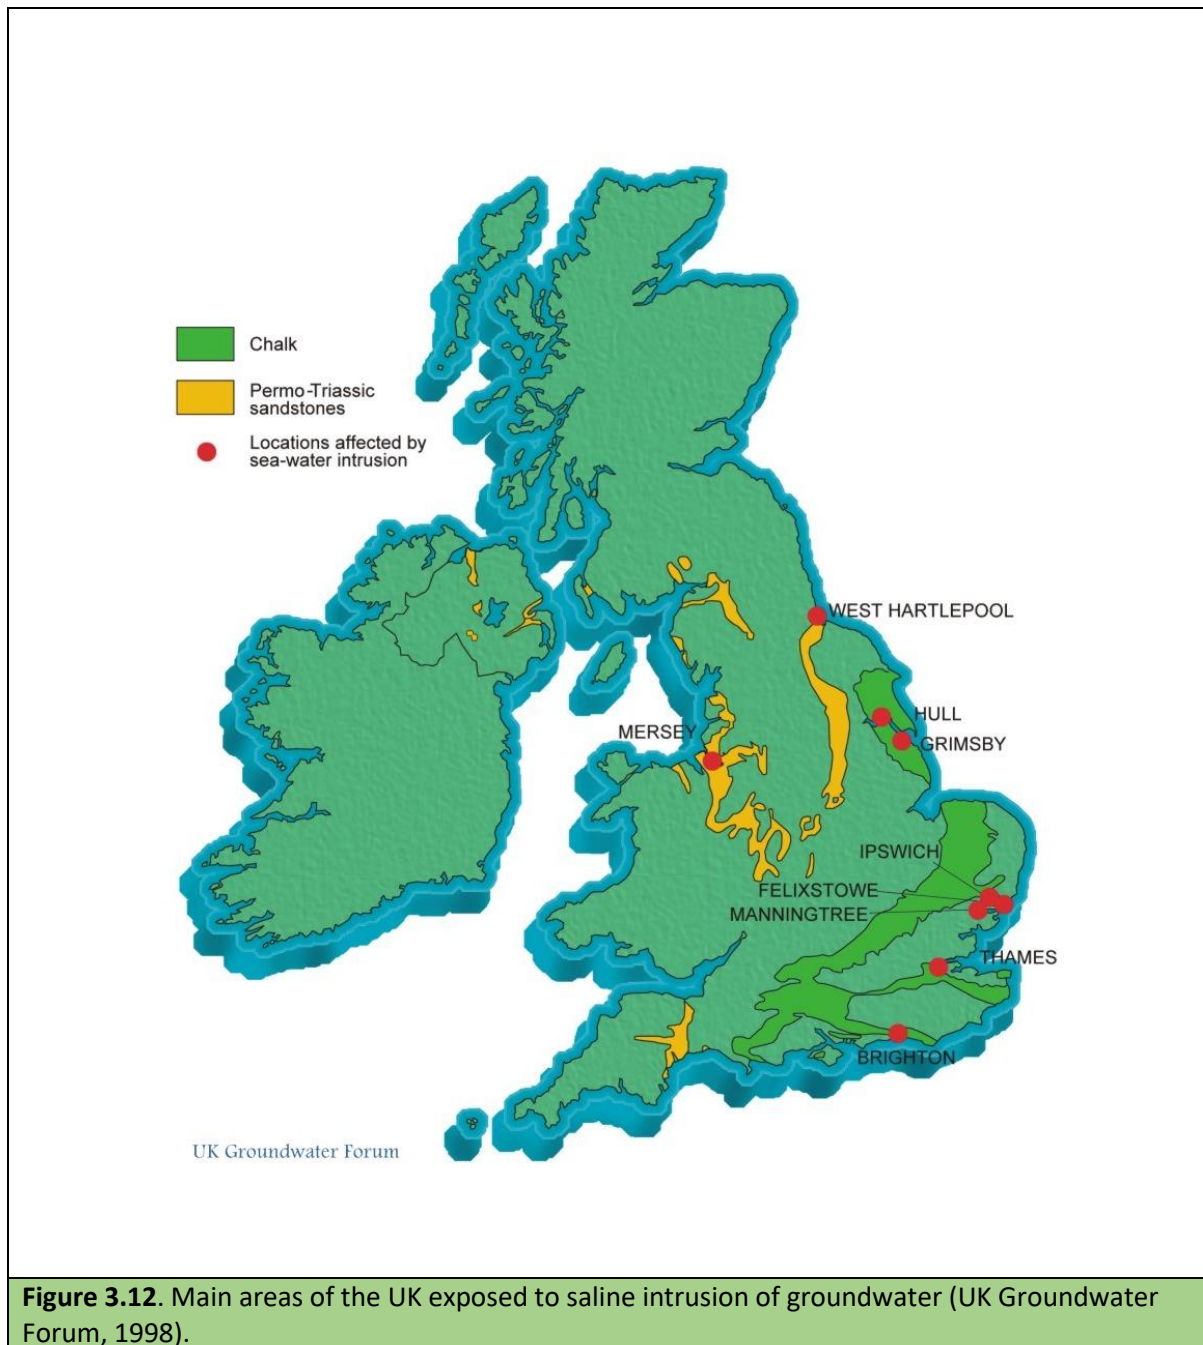

### 3.11.1 Current and future level of risk (N10)

#### 3.11.1.1 Current risk (N10)

Currently this is a localised risk in the UK. Saline intrusion can affect groundwater as a result of over-abstraction (via pumps, boreholes or wells). The hydraulic gradient from the land to the sea can be weakened, and sometimes reversed, by the removal of freshwater. Hydraulic gradients can also be disrupted where land elevation lowering has occurred due to drainage and subsidence (e.g., the Fens), which may involve pumping stations. Because sea water is denser than freshwater, the intrusion will (at first) occur in the lower parts of the aquifer, with the freshwater-seawater boundary moving landwards. The intrusion of salt water into coastal aquifers can impact on water availability in those districts, which can impact on agriculture. Some water abstraction also occurs seasonally in estuaries based upon the relative predominance of freshwater and saltwater (which follows a well-defined pattern based on tidal flows), and the abstraction regime is therefore designed to take account of salinity constraints.

Risks to coastal aquifers are a consequence of sea-level rise causing saline intrusion and from reduced summer rainfall and aquifer recharge, particularly for eastern and southern England where some aquifers provide public water supplies (e.g., Dungeness in Kent, which is underlain by the Denge gravel aquifer). This risk therefore requires balancing abstraction and recharge to prevent saline intrusion, as informed by detailed monitoring, and, if necessary, abstraction restrictions during drought periods. Abstraction for agricultural use through groundwater boreholes currently tends to be smaller scale compared to public water supplies.

The overall exposure to salinization of coastal aquifers for the UK is not known. An indicative map of exposure is provided in Figure 3.12 but this is dated and more detailed data would be required for a full national risk assessment. In addition, saline intrusion may occur through drift deposits, as notably in coastal areas of the Fens and East Anglia where shallow groundwater basins are below sea level. Our assessment is that this risk is a lesser issue for Scotland and Northern Ireland, both because the underlying geology means that surface water resources dominate over groundwater resources, and because relative sea-level rise to present has been generally lower in the northern UK due to local land uplift. Wales may be expected to have some localised exposure, but to a rather lesser extent than England.

Regarding impacts on water quality, 13 failures to meet good ecological status as notified under Water Framework Directive (WFD) reporting (Environment Agency; SEPA; NRW; DAERI) were attributed to saline intrusion in England and Wales, and 12 in Scotland in 2014. However, these make up a very small proportion (<1%) of total failures. Only one water company in southern England has identified constraints from salinization in its planning tables for sources and licensing agreements (although this is not a mandatory requirement), with 2 licenses affected (a total of up to 22.98 Ml/d, although the deployable output is lower: up to 15.36 Ml/d). Similarly, while the effects of water salinization on agricultural land currently remain localised, detailed risk mapping at national scale is not presently available. Areas of agricultural land exposed to surface flooding risks have been identified through topographic analysis (see Risk N6) but the more refined assessment required to

assess groundwater saline intrusion risks is usually only defined locally and requires detailed hydrogeological data.

### 3.11.1.2 Future risk (N10)

The magnitude of future risk is strongly related to the magnitude of sea-level rise and will also be influenced by shifts in hydraulic gradient related to changing precipitation patterns. In addition, the risk will be influenced by water abstraction rates in exposed areas; if these are not adjusted to allow for the increased risk and continue as before (or even possibly increase under some socioeconomic scenarios) then they are likely to significantly exacerbate the risk. However, with regard to public water supplies, the current abstraction strategy does already allow for seasonal variations.

Our assessment is that the future risk to aquifers is therefore expected to gradually increase with sea level rise and may be more pronounced during drought periods. As intense cyclonic conditions influencing storm surges most commonly take place outside summer months, their coincidence with previous drought conditions is relatively low. However, if drought conditions extend into the stormy autumn season, then the combined effect may produce a more extreme risk of intrusion. No evidence is available to identify exposure of new areas beyond those currently affected (primarily eastern and south east England) but it is possible that some water resource zones with high demand elsewhere in the UK may also experience a relative increase in risk. As sea level rise values are lower in Scotland and Northern Ireland, exposure is lower, and also public and agricultural water supplies there have a smaller reliance on coastal aquifers.

Although UKCP18 has provided median and upper-end sea-level rise projections that are higher than UKCP09, this increase is by itself not expected to significantly change the magnitude for this risk based on current evidence of exposure and sensitivity. An exception to these findings would occur if an extreme High++ future climate scenario was to be realised. As discussed in Chapter 1 (Slingo, 2021), extreme sea level rises reaching 2m by 2100 cannot be excluded as a possibility despite their much smaller likelihood based on current evidence. However, there is currently no evidence to identify how big a difference such a H++ scenario would make in terms of exposure and implications for public water supply and agricultural land.

With regard to aquifers, in a scenario consistent with approximately 4°C global warming at the end of the century<sup>21</sup>, the recharge season for groundwater may on average become shorter in future, with greater amount of recharge “squeezed” into fewer months (Mansour and Hughes, 2017; Mansour *et al.*, 2018). Although groundwater recharge continues under this future scenario, it also becomes more irregular (‘lumpy’) and if precipitation inputs fail for one of these critical recharge months, then the aquifer may become more vulnerable to increased drawdown, especially if abstraction rates are not reduced in response. However, no known research has investigated this issue yet in the context of implications for saline intrusion.

---

<sup>21</sup> UKCP09 perturbed-parameter ensemble with the HadRM3 regional climate model driven by the SRES A1B scenario

#### 3.11.1.3 Lock-in (N10)

There are lock-in risks but only if abstraction rates continue as present, or increase, and are not adjusted to the changing climate-related exposure from sea-level rise.

#### 3.11.1.4 Potential thresholds (N10)

There are thresholds associated with sea-level rise, although the critical value be dependent on local contexts. There is also likely to be a threshold value for safe abstraction, as defined relative to local precipitation rates and the pattern of groundwater recharge.

#### 3.11.1.5 Cross-cutting risks and inter-dependencies (N10)

Abstraction rates will be influenced by demand for water, both through the public water supply, and to sustain agricultural production (Risk N7). Reduced water quality (and hence supply) may impact on water availability for different uses, including agriculture, and may also have consequences for freshwater biodiversity (Risk N11). An important interaction may also exist with coastal zone management and potential further implementation of managed realignment schemes (see Risk N17), because, by altering the salinity regime in estuaries, these may modify the saline intrusion risk in that location. However, presently there is no evidence to show the scale of this interaction.

#### 3.11.1.6 Implications of Net Zero (N10)

No evidence was identified. Potentially, the impetus in the Net Zero scenario to intensify agricultural production may increase water demand in at-risk areas and therefore increase the frequency of salinity intrusion. This could then impact on water availability and production capability, although problems could be avoided through good planning and management.

#### 3.11.1.7 Inequalities (N10)

No evidence for impacts on inequalities were identified in relation to climate change risks to aquifers and agricultural land from saltwater intrusion.

#### 3.11.1.8 Magnitude scores (N10)

Magnitude categories are based on expert judgement of existing and expected impacts on water quality due to limited quantitative data. Risk magnitude (national scale) is assessed as low at present and continuing as low for the future climate projections. The exception is for 4°C in the 2080s, for which the combination of climate change and socioeconomic factors means we have identified risks in England and Wales as of 'unknown' magnitude, with an increased possibility that magnitude may increase from low to medium. For Scotland and Northern Ireland, the lower level of exposure suggests that a low-risk magnitude would still apply. Confidence in this categorisation is higher than may be expected based upon evidence of impacts because it would be expected that, if the current risk was higher, more negative impacts would have been detected and reported through monitoring data and resource surveys (e.g., water company reports). We also use this current absence of impacts when assessing confidence in risks from future scenarios. It should be noted, however, that if an extreme High++ sea-level rise scenario were to develop (i.e., higher than the assumed

‘reasonable worst-case scenario’), as cannot be excluded especially in a pathway to 4°C global warming at the end of the century, then this risk would likely be in a higher magnitude category due to increased exposure.

**Table 3.32** Magnitude scores for risks to aquifers and agricultural land from saltwater intrusion

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Low  (High confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Unknown
<b>Northern Ireland</b>	Low  (High confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)
<b>Scotland</b>	Low  (High confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)
<b>Wales</b>	Low  (High confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Low  (Medium confidence)	Unknown

### 3.11.2 Extent to which current adaptation will manage the risk (N10)

#### 3.11.2.1 Effects of current adaptation policy and commitments on current and future risk (N10)

Abstraction is regulated by government policy and at present is licensed by the regulatory authorities in each country in accordance with the water quality requirements of the Water Framework Directive. As discussed above, this acts to identify and report impacts on water resources in combination with water company plans. In general, although there remain important uncertainties, vulnerable aquifers are known from their hydrogeological properties and can be monitored, and alternative resources identified. Measures to manage the risk are already in use and will require further review based upon ongoing monitoring referenced against ongoing climate change. The licensing system is currently being reformed which is expected to provide improvements in the sustainability of the resource. The gradual transitional time of saline intrusion of aquifers (even with higher rates of sea level rise) should provide time to adapt, except perhaps in the extreme case of a High++ scenario (e.g., due to accelerated mass loss from ice sheets, see Chapter 1: Slingo, 2021).

Our assessment is that adaptation is therefore presently occurring through existing policy frameworks, although not explicitly referenced to climate change. This is more defined for England and Wales (or more specifically, for specific regions based upon hydrogeology) and to a rather lesser extent for Scotland but this would be consistent with an expected lower risk exposure. In addition to an assumed continuation of water body status reporting consistent with commitments previously made for the EU WFD, monitoring and responses may be activated through nature conservation legislation. For example, in Wales, efforts to mitigate saltwater intrusion are in part delivered through policy related to the Conservation of Habitats and Species Regulations 2017. In Scotland, SEPA and Scottish Water measure saline levels as part of their formal water quality testing and abstraction management programmes so any trends are expected to be detected using existing programmes of monitoring. A different situation exists in Northern Ireland where some water bodies are shared as international transboundary resources that are managed with the Republic of Ireland, but again there are no known issues at present regarding saline intrusion for these water bodies. At the time of assessment, there are uncertainties regarding the future status of groundwater management between Northern Ireland and the Republic of Ireland regarding policies following UK exit from the EU (previously defined through WFD obligations), highlighting that a transboundary groundwater agreement may be beneficial to co-ordinate responses.

#### 3.11.2.2. Effects of non-Government adaptation (N10)

Water companies currently adjust their abstraction regime based upon knowledge of the risk of saline intrusion from monitoring, therefore adaptive capacity already exists. Agricultural abstraction is more localised and controlled through the licensing system including licenses of right (issued in perpetuity, linked to assumed 'grandfather rights' etc.) and time-bound licenses (subject to regular review) (Parliamentary Office of Science & Technology, 2017). Not all of the allocated licensing rights are currently used and if used to their fullest extent may cause additional problems in some locations. Regular update of license agreements could be adjusted to manage the risk of salinization in exposed areas.

Farmers experiencing local salinisation problems have in some locations adapted to the risk by digging 'seepage pits' to rapidly abstract freshwater lenses. Alternatively, some crops can cope with irrigation by brackish water and can still provide viable produce (e.g., potatoes). However, the long-term effects of these strategies are unknown.

#### 3.11.2.3 Barriers preventing adaptation to the risk (N10)

Increased agricultural water demand and groundwater abstraction may increase the risk of groundwater intrusion unless appropriately regulated. Similarly, increased household water demand (either per capita demand or through new housebuilding) in some locations may also place additional stress on groundwater reserves, leading to increased intrusion risk, unless regulated.

#### 3.11.2.4 Adaptation shortfall (N10)

The risk to aquifers and agricultural land from saline intrusion is low at present (based upon existing reporting) and most likely to remain low in the future (extrapolated from existing risk exposure), except in instances of more extreme sea-level rise (most notably a High++ scenario). Additional

stresses from human pressures (see below) also need careful monitoring to understand the combined risk from climate and socioeconomic change. Continuing current risk management procedures therefore appear adequate to maintain risk at a low level by 2100 as long as monitoring efforts continue, although some local areas may experience an increased exposure especially during drought conditions. Confidence is medium in this assessment based on current reporting, but some limitations can be identified in existing knowledge both regarding the changing level of exposure and the intrinsic vulnerability of different groundwater systems and their users to changes in risk factors.

### 3.11.2.5 Adaptation Scores (N10)

<b>Table 3.33</b> Adaptation scores risks to aquifers and agricultural land from saltwater intrusion			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Yes	Yes	Yes	Yes
(Medium confidence)	(Medium confidence)	(Medium confidence)	(Medium confidence)

### 3.11.3 Benefits of further adaptation action in the next five years (N10)

Increased pressure on aquifers at risk of saline intrusion from agricultural water demand could be alleviated by use of alternative water resources. For example, better storage and use of excess winter rainfall and other methods to maximise sustainable use of surface water resources (e.g., rainwater harvesting and on-farm reservoirs) could act to conserve groundwater resources at a sustainable level and mitigate against saline intrusion (although also noting that some surface water is essential for groundwater recharge). Policy guidance and water abstraction licensing arrangements would need further refinement to incentivise such arrangements as consistent with regular review of regulatory limits.

As the key climate change drivers for this risk are relative sea-level rise and seasonal precipitation regimes, this risk topic would be an appropriate one to further investigate through the operational use of adaptation pathways. This would require enhanced collation and use of knowledge on the relationship between climate change drivers and safe abstraction rates at specific locations. By identifying and defining trigger points in the existing policy review cycles, linked to both the rate of sea-level rise and the recharge rate of the vulnerable groundwater resource (as linked to changing precipitation patterns), different pathways for achieving sustainable abstraction could then be defined that better recognised future uncertainty.

#### 3.11.3.1 Indicative costs and benefits of additional adaptation (N10)

There are some studies which include the impacts (in economic terms) of climate change on saltwater intrusion (e.g., see Brown *et al.*, 2011; Hinkel *et al.*, 2014), but these tend to be aggregated alongside flood damages, and are low in comparison, and these studies do not assess the costs and benefits of adaptation for salt water intrusion. There are also some case studies, but these tend to

focus on urban areas, where there are very high economic costs (from contamination) and thus very different benefit to cost ratios. There is therefore a low-regret action to investigate this impact further (i.e., the value of information relating to saltwater intrusion adaptation options for agricultural land), and a more iterative approach which includes monitoring is generally considered a low regret option. There are examples of adaptation options to prevent vulnerable aquifers from saline intrusion, including saltwater intrusion barriers and freshwater injection (Zhu *et al.*, 2010) and cost-benefit information exists for these measures from countries with greater saline intrusion problems. These generally show when aquifers are in use, measures have economic benefits when compared to subsequent water treatment and restoration costs after contamination occurs.

### 3.11.3.2 Overall urgency scores (N10)

<b>Table 3.34</b> Urgency scores for risks to aquifers and agricultural land from saltwater intrusion				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	Further Investigation	Watching Brief	Watching Brief	Further Investigation
<b>Confidence</b>	Low/Medium	Low	Low	Low/Medium

Given the projected low levels of future risk and adequacy of current risk management procedures to adapt to the risk, continuing with current procedures for the next 5 years until the next CCRA seems suitable. However, because risk is localised in specific areas, and because some important knowledge gaps have apparently been identified, England and Wales are identified as areas of the UK that would benefit from 'Further Investigation' to provide additional clarification on exposure and vulnerability issues. Scotland and Northern Ireland are assigned a 'Watching Brief' assessment due to the lesser scale of risk exposure, although here current evidence is also more limited (presumably consistent with assumed lower exposure and vulnerability to this risk).

Areas of focus:

- Liaise with water companies and water users to further investigate spatial and temporal patterns in risk exposure and vulnerability.
- Continue to monitor and report on impacts for aquifers to assess whether risks are increasing.
- Develop forward projections based upon different climate change and socioeconomic scenarios to assess robustness of regional and national resources and implications for adaptive resource management.

### 3.11.4 Looking ahead (N10)

An improved national assessment of risk exposure for vulnerable aquifers under different UKCP18 projections would be beneficial in advance of CCRA4, and subsequent work to understand associated implications for public water supply and agricultural demand.

### 3.12 Risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts (N11)

- Risks from reduced water availability and higher water temperatures will increase the degradation of freshwater habitats and compromise the viability of some freshwater species.
- The magnitude of current and future risks is judged to be medium in the 2050s on pathways to both 2°C and 4°C global warming by the end of the century. By the 2080s, it remains as medium on the 2°C warming pathway, but increases to high magnitude on the 4°C warming pathway.
- This risk has been assessed as needing more action due to the incomplete base of evidence for climate impacts on freshwater ecosystems at present, and the shortfall in adaptation measures that exist.

#### Introduction

Freshwaters provide the UK with a wide array of socioeconomically important ecosystem services, including water supply (for drinking, agriculture, and industry), peat extraction, pollution removal, and recreation (e.g., fishing and tourism). The asset value of freshwater services to the UK (2014-2015) has been estimated at approximately £39.5 billion (Office for National Statistics, 2017), although the estimate should be interpreted as the minimum value of the habitat, as it does not include all relevant ecosystem services since some cannot be measured. Underpinning these important assets and services are biodiversity and ecological processes that are sensitive to climate change. While CCRA2 identified freshwater habitats as being particularly vulnerable to reduced water availability in the face of climate change, freshwater species and biodiversity are highly sensitive to the direct and indirect effects of temperature as well.

The potential impacts of climate change on freshwater are numerous and complex. Direct effects of changes in temperature occur through species behavioural and physiological responses. Indirect effects occur when temperature change impacts species interactions and habitat features, which in turn affect, or can cause the loss of, sensitive species (Moss, 2014). For obligate aquatic species (e.g., fish, plankton) water temperature is of direct relevance to climate change impacts. However, for other species, air temperatures will also be important e.g., water birds. Furthermore, migrant species will likely be affected by temperature change throughout their migratory route, including wintering and breeding grounds.

In addition to impacts on biodiversity, higher temperatures can directly increase the possibility of water quality problems through increasing the rates of biological and chemical processes, especially algal growth rates and nutrient cycling (Charlton *et al.*, 2018; EA, 2019b). However, indirect effects are also possible, through temperature effects on lake mixing patterns that in turn influence nutrient cycling and algal growth (Radbourne *et al.*, 2019). Additional complexity arises because climate

change interacts with other stressors, such as nutrient enrichment, to affect the state of freshwater ecosystems.

A recent assessment of climate-driven thresholds (Jones *et al.*, 2020) focused on four potential risks at UK scale: algal blooms in lakes, algal blooms in rivers, loss of habitat for sensitive fish species, and changes in the composition of lake plankton populations. Given currently available evidence, economic valuation of risk was possible only for algal blooms in lakes. Even so, the costs of this risk alone, based on a single UKCP18 model variation, were projected to increase from £173 million at baseline (2001-2010) to £295 million under a scenario of 2°C global warming and £481 million with 4°C global warming<sup>22</sup>. Given the lack of suitable data to place a monetary value on many other climate change effects, we must view these figures as a minimum estimate of economic impact.

At present, given the available evidence, the magnitude of current and future risks is judged to be medium in the 2050s on pathways to both 2°C and 4°C global warming by the end of the century. By the 2080s, it remains as medium on the 2°C warming pathway. However, with increasing volumes of evidence on specific impacts and sensitive species, this risk could increase. Thus, the magnitude is scored as high for the 2080s with 4°C global warming, due to the likelihood of greater changes in temperature, river flows and water quality under this scenario. Given the currently incomplete knowledge of climate impacts on freshwater ecosystems, and the current shortfall in adaptation measures, there is a need for more action, combined with further investigation on the scale of risk and effectiveness of these measures.

### 3.12.1 Current and future level of risk (N11)

Climate change can impact freshwater habitats and species both directly (e.g., species growth and survival responding to temperature change and alterations to flow regimes) and indirectly (e.g., effects on species manifest through their interactions with predators and competitors, or through climate effects on habitat conditions). It is therefore necessary to consider the evidence for climate impacts on physical, chemical and biological features of fresh waters. In general, freshwater species may respond to climate change through changes in their abundance, life history characteristics, distribution, and seasonal behaviour.

Note: currently available evidence is not sufficient to allow us to report on the current and future level of risk and opportunity for each UK country separately.

#### 3.12.1.1 Current risk (N11)

Given the multifaceted nature of climate change effects on freshwater habitats and species, recent evidence is organised into a series of impact types.

---

<sup>22</sup> UKCP18 regional model driven by a global model with the RCP8.5 emissions scenario, reaching 2°C global warming in 2025-2034 and 4°C global warming in the 2060s. This rapid rate of warming is a low-probability, high-impact scenario but can be used to infer impacts of the same levels of warming reached at later dates.

### 3.12.1.1.1 Impacts on thermal regime

An important consideration for freshwater climate impacts is the relationship between observed air temperature change, and corresponding changes in water temperature. There is not a simple 1:1 relationship between these measures (Defra, 2014). Recent modelling work, using current stream and air temperature data from across Scotland, showed that this relationship is spatially and seasonally variable, dependent on local topography and land cover (Jackson *et al.*, 2018). For example, at maximum air temperatures of 25°C, maximum water temperatures under 100% riparian woodland cover are estimated to be approximately 2 °C lower than under 0% cover. Water temperature and the thermal effects of riparian shading may themselves depend upon large-scale atmospheric phenomena. Analysing ~1 million temperature records across England, Wilby and Johnson (2020) showed that summer river water temperatures were especially sensitive to variations in the North Atlantic Oscillation (NAO) in northeast and west England, and at sites >300m elevation. In a parallel analysis of data from the Loughborough University Temperature Network, they also showed that the NAO can influence the thermal effects of riparian shading, with temperature differences between open and shaded sites being greater under a positive NAO. The sensitivity of river water temperatures to air temperature is also influenced by hydrometric area and elevation. Work originating beyond the UK further supports the likelihood of spatially-variable water temperature responses to air temperature change. For example, high groundwater contributions to streamflow (high baseflow) in some systems may serve to dampen stream water temperature change (Carlson *et al.*, 2017, Briggs *et al.*, 2018). Global-scale studies (including UK fresh waters) show similar among-habitat variability for standing waters: O'Reilly *et al.* (2015) found that trends in lake surface water temperatures can exceed or fall below coincident air temperature trends. An investigation into the salmonid recruitment crash in Welsh rivers found that that a combination of high water temperature during spawning, and low water temperature together with high flows during emergence might have led to the 2016 juvenile salmon crash, but that trout were less affected, although recruitment was poor (Gregory *et al.*, 2020).

Multi-decadal data sets for UK lakes are rare, but exceptionally long-running data from four “sentinel” lake basins in Cumbria, collected by the UK Centre for Ecology and Hydrology, show that 4 of the 5 warmest years since 1945 have occurred post-2000 (Muchan, 2020). Furthermore, recent analysis of warm-season lake surface water temperatures in 127 European lakes (including some from the UK) demonstrated a warming trend of  $+0.39 \pm 0.03^{\circ}\text{C decade}^{-1}$  in the 1995-2019 period (Blunden and Arndt, 2020), while average water temperature changes of  $+0.34^{\circ}\text{C decade}^{-1}$  were reported for 235 globally-distributed lakes between 1985 and 2009 (O'Reilly *et al.*, 2015). Previous analyses of river water temperatures across England and Wales (1990-2006), reported in CCRA2, also showed that, on average, mean water temperatures have increased by  $0.03^{\circ}\text{C y}^{-1}$  (Orr *et al.*, 2014).

### 3.12.1.1.2 Ecological effects via altered river flows and water quantity

CCRA2 identified freshwater habitats as being particularly vulnerable to reduced water availability in the face of climate change. The impacts of drought can fundamentally change freshwater biodiversity. For example, in river macrophyte communities, resident species can be eradicated, allowing more opportunistic species to establish (Lake, 2011). Aquatic plants are of fundamental

importance to such ecosystems; when they die, organic material is deposited on the riverbed and brink, serving as a high-moisture refuge for other biota during drought conditions (Lake, 2011). Drought can also lead to a loss of horizontal, longitudinal and vertical habitat connectivity, while after a drought, sediments and nutrients are washed into the river and sulphates can be released from soils (Dobel *et al.*, 2019). Drought or low flow conditions will also reduce the dilution of pollutants, as well as nutrient inputs from sewage treatment works, which can lead to eutrophication (see below).

In addition to water scarcity itself, drought also leads to risks associated with water temperature. Under low-water conditions, water temperatures in pools can surpass the upper thermal limits of salmonid species, resulting in thermal stress (Elliott and Elliott, 2010). High temperatures during periods of water scarcity in summer 2018 led to an order to stop fishing in the River Test in Hampshire, England (Environment Agency, following the recommendation that catch and release angling is not practiced at mid-morning water temperatures in excess of 18°C). During 2018 there were localised fish kills in UK rivers resulting from associated de-oxygenation events (Dobel *et al.*, 2019).

As discussed in previous CCRA, for some catchments that have extensive areas of high ground, most notably in the Scottish Highlands and Cairngorms, the changing pattern of snow cover (extent and depth) can have an influence on hydrology and ecology. There is good evidence for declining snow cover in the British uplands, although there is high interannual variability and significant spatial and altitudinal relationships related to prevalence of large-scale atmospheric circulation patterns including the North Atlantic Oscillation (Kay, 2016; Brown, 2019). There is also good evidence that for snowmelt-sensitive catchments, reduced snow cover means that maximum peak flows tend towards occurring earlier in the winter season (rather than spring), with simulation models showing this relationship extends into the future (Bell *et al.*, 2016). This reduction in snow cover storage may also produce a more flashy hydrological regime and potentially higher peak flows due to more direct runoff in sensitive catchments, but this will also be strongly dependent on other changes in seasonal precipitation amounts for that catchment. In terms of ecological effects, the evidence is weaker: severe floods can damage important fish spawning grounds, notably for salmonids, but fish have also been negatively affected by a range of other pressures that have impacted on spawning.

#### 3.12.1.1.3 Water quality

Climate change impacts on water quality can impact biodiversity, the provision of clean water for consumption and associated water treatment costs, and the recreational potential of fresh waters. There is great potential for patterns of nutrient loading and enrichment to be impacted through climate driven changes to nutrient transport and biogeochemical processing within water bodies (Defra, 2014), with resulting impacts on species and habitat conditions. The complex interaction between water temperature and water quality is exemplified by a recent pan-European analysis (including data from numerous UK sites), which showed that, while rising temperatures could affect water quality by stimulating the growth of potentially-toxic “blue-green algae” (cyanobacteria), these effects vary greatly among lake types (varying in geographic location, water colour, alkalinity and mixing regime, Richardson *et al.*, 2018). Noting such dependencies, CCRA2 suggested that more action is needed to reduce pollution and improve the ecological condition of wetland habitats

through encouraging the wider uptake of management practices to help tackle the impact of interacting stressors. There are strong financial, as well as environmental, reasons for prioritising the restoration of water bodies.

To date, progress on improving the water quality and ecological condition of UK freshwater habitats has been mixed. The percentage of designated freshwater sites in favourable condition is improving, though freshwater SSSIs only represent approximately 8% of the total area of freshwater habitats in England (CCC, 2019b). Available data suggest that, between 2009 and 2019, there was little change in the overall number of surface water bodies in the UK awarded high or good ecological status according to the Water Framework Directive (WFD) (35-37% waterbodies, Defra, 2020a). In Northern Ireland, there has been a significant decline in lake status as part of WFD reporting since 2018. In 2018, 5 of the 21 lake water bodies were classified as ‘good’ or better and 16 lake water bodies were classified as ‘moderate’ or worse. In 2020, only 1 of the 21 lake water bodies were classified as ‘good’ or better status and the remaining 20 lake water bodies classified as ‘moderate’ or worse (DAERA, 2020).

Though much research has been conducted on the impacts of climate change on nutrient delivery and cycling, we recognise that there are many additional pollutants that could impact upon water quality and ecological state (e.g., organic pollution, ammonia, nanoparticles, metals, microplastics). The interdependencies between climate change and the impacts of these pollutants are worthy of further investigation.

#### 3.12.1.1.4 Species abundance and distribution

Recent evidence suggests that climate change is already affecting the abundance and distribution of freshwater species throughout the UK. For example, analyses of long-term (1981-2005) invertebrate data from the Llyn Brianne catchment in Wales revealed long-term declines in invertebrate abundances, and some local extinctions, that are attributable to warming (Jones *et al.*, 2013). Such impacts may be mediated by dissolved oxygen concentrations (Verberk *et al.*, 2016). Temperature can also affect population growth and body size in freshwater animals, including top predators like pike (Vindenes *et al.*, 2014), and can have cascading effects through food webs (Edeline *et al.*, 2016). Furthermore, in the UK, the small wintering population of smew (*Mergellus albellus*) is being negatively affected by increasing winter air temperatures and may be at risk of loss here, due to the species’ redistribution in response to climate change (Pavón-Jordán *et al.*, 2015). However, the UK is important for the species when winters in the central and north eastern part of its range are severe.

However, freshwater species are responding to a complex array of interacting stressors (Birk *et al.*, 2020), which may exacerbate, dampen, or dominate climate change impacts. An analysis of family-level distributions and nationwide trends in prevalence of macroinvertebrates, using data for 1991–2011 from >2300 rivers across England and Wales, showed that longer-term changes in prevalence were linked to water quality (concentrations of the nutrients nitrate and phosphate and overall organic loading), with little evidence of the influence of increasing water temperatures (Vaughan and Ormerod, 2014). For example, the small northward expansion of the range of many taxa was accounted for by large improvements in water quality in northern England. However, shorter-term

variations were linked to water temperature and nutrient concentrations. In fact, it has been suggested that water quality improvements across England and Wales have aided in offsetting the impacts of 0.64°C of warming on macroinvertebrate communities (Vaughan and Gotelli, 2019). As noted by the authors of this study, though, our potential to mitigate against climate impacts through water quality improvement is finite.

#### 3.12.1.1.5 Phenological shifts

Shifts in the seasonal timing of biological events (e.g., migration, breeding, flowering) are widely accepted to be part of the ecological “fingerprint” of climate change. These shifts are of concern given the potential for important species interactions to be disrupted, with consequences for ecosystem structure, function, and service provision. Broad-scale seasonal shifts are already apparent across the UK, based upon the analysis of long-term records (Thackeray *et al.*, 2010; 2016).

As a more specific example, the timing of salmon migration in rivers has been found to be correlated with freshwater temperatures up to about 10°C, levelling off at higher values (Otero *et al.*, 2014). In Scotland, the day of the year by which 25% of smolts have migrated has advanced by about 1.5 days per decade over the last 47 years (Malcolm *et al.*, 2015). Climate impacts upon Scotland's Atlantic salmon populations are of both national and international importance, since these stocks account for approximately 75% and 30% of estimated UK and European salmon production (pre-fishery abundance) respectively (ICES, 2016). Similarly, fry emergence dates for brown trout are affected by stream water temperature, becoming earlier under warmer conditions (Elliott and Elliott, 2010). Other climate-sensitive environmental factors can also have an effect on seasonal timing. For example, earlier Atlantic salmon migration was found to occur when river flows were low, but increasing (Otero *et al.*, 2014).

Temperature increase could also affect the seasonal behaviour of land-locked fish populations. Rising water temperatures in Windermere, England's largest lake, are associated with a shift towards earlier perch spawning (Thackeray *et al.*, 2013). However, changes in perch spawning have not kept pace with similar shifts in seasonal plankton food resources, with detectable effects on fish recruitment (Ohlberger *et al.*, 2014). The effects of shifting seasonality are relatively understudied in freshwater compared to terrestrial ecosystems (Samplonius *et al.*, 2021, but may have consequences for UK recreational fisheries.

Changing water temperatures also have the potential to fundamentally alter life cycles of aquatic insects. In the River Dove (English Peak District) the mayfly *Ephemera danica* was shown to shift from a two-year to one-year life cycle with greater growing degree day accumulation under warmer conditions (Everall *et al.*, 2015). It was inferred that this shift to a one-year life cycle would lead to an increased vulnerability of the insects to adverse weather, and reduced reproduction (fecundity). The shift in life cycle was not, however, observed in river reaches affected by cool groundwater inputs, which potentially act as thermal refugia.

### 3.12.1.1.6 Extreme events

Variability is a natural feature of freshwater ecosystem behaviour (e.g., predictable seasonal variations in flow, water level and temperature). However, there is concern that future increases in the frequency, intensity and duration of extreme events, beyond the range of natural variation, will have significant impacts on water quantity and quality, the structure of the physical environment, habitat availability and connectivity, and biodiversity (Jones *et al.*, 2013). The potential ecological outcomes of extremes are wide-ranging, depending on the nature of the extremes (e.g., flood, drought, heatwave), the space and time scales over which they occur, and the physical, chemical and biological features (including species traits) of impacted ecosystems.

Though there is great variability in the likely impacts of extreme events, documented examples are informative:

1. In October 2017, **Storm** Ophelia passed over the UK and increased wind energy at the surface of Windermere 25-fold, deepening mixing in the lake and causing an upwelling of cold, oxygen poor water (Woolway *et al.*, 2018). These upwelling waters flowed into the main outflow of the lake, the River Leven, resulting in a 48% reduction in dissolved oxygen concentrations. This example illustrates the profound effects that extremes can have on fresh waters, though it should be noted that these effects are likely to be highly variable among lakes and catchments (Stockwell *et al.*, 2020).
2. In 1997, a 1-in-100+ year **flood** occurred on the River Wansbeck, in Northumberland. This event damaged stands of emergent vegetation, including species such as the branched bur-reed (*Sparganium erectum*) and common club-rush (*Schoenoplectus lacustris*). Vegetation was uprooted by scouring flows and erosion that destroyed plant habitat, with consequent effects for organisms dependent upon this habitat (Jones *et al.*, 2013).
3. **Drought** conditions during the 1989-1992 period had a range of impacts upon chalk streams throughout south east England, including reductions in invertebrate abundance and species turnover in plants communities, which transitioned from non-aquatic to wetland and classic aquatic plants as flows resumed (Jones *et al.*, 2013). Recent large-scale outdoor mesocosm experiments suggest that frequent drought conditions may affect stability of stream ecosystem functions, with potential consequences for ecosystem service provision (Leigh *et al.*, 2019).
4. In 2016, in many rivers in England and Wales there was poor recruitment of juvenile salmonids, particularly salmon fry, which was thought to be caused by **unusually warm winter temperatures and extreme flows** which adversely affected spawning success (ICES, 2018).
5. **Thermopeaking** (rapid changes in water temperature) may occur in response to weather conditions. For example, sensor data from the River Dove (English Peak District) suggest that river temperatures can change suddenly in response to bright sunshine, heavy snowfall/melt, and intense rainfall (Wilby *et al.*, 2015). The most extreme temperature changes recorded in this study were +2.8 °C h<sup>-1</sup> for intense rainfall, -1.3 °C h<sup>-1</sup> for snow melt, and +1.2 °C h<sup>-1</sup> for intense solar heating. The impacts of such thermal extremes on freshwater biota require investigation.

While the impacts of extreme events can be profound, recovery can potentially occur quickly. The rate of population recovery varies greatly among species, according to their traits, but also depends on the availability of refuges in which species can survive extreme events, and habitat connectivity.

Furthermore, the combined effects of multiple anthropogenic stressors can hinder recovery from extremes (Jones *et al.*, 2013). Reported post-extreme recovery times are variable. Woodward *et al.*, (2015) report that, in the Glenfinish River (Ireland), a catastrophic 1986 summer flood triggered a 10-fold decline in invertebrate abundance. While most populations returned to their pre-disturbance state in less than 3 years, some took up to a decade to recover. It should be noted that the impacts of extreme weather are also context dependent. For instance, a study in Switzerland suggested that water temperature responses to heatwave conditions may be dampened in streams fed by snow melt, and receiving cool water from reservoir releases, when compared to lowland rivers (Piccolroaz *et al.*, 2018). To aid management and adaptation, we need to advance our understanding of what determines the sensitivity of UK freshwaters to extreme events.

#### 3.12.1.2 Future risk (N11)

UKCP18 climate scenarios suggest substantial increases in winter daily precipitation, both frequency and intensity, especially in western Britain (Chapter 1: Slingo, 2021). This has implications for river flows, flood risk and water resource management. Similarly, summers are projected to be hotter and drier, with the potential for more summer drought. In our view, these climate changes are likely to impact the state of freshwater ecosystems and water regulation services (water quality, water flows) in the future. Impacts on freshwater species and habitats will occur through increased temperatures, changes in patterns of rainfall and river flow, knock-on effects on nutrient inputs and cycling which will exacerbate eutrophication impacts, extreme events, and spatio-temporal changes in species distributions.

##### 3.12.1.2.1 Impacts on thermal regime

Climate change is projected to further impact the thermal regime of UK fresh waters. By combining global-scale satellite-derived lake temperature data and a climate change scenarios reaching approximately 2°C and 4°C global warming by 2100<sup>23</sup>), Maberly *et al.* (2020) estimated that between 12% and 27% of the world's larger lakes would shift to a thermal regime characteristic of present-day lower latitudes by 2080-2099. UK lakes were included in this study and are at risk of such a shift.

Future changes in water temperatures are likely to be spatially and seasonally variable, due to the impacts of local habitat features (e.g., riparian shading). Through statistical modelling of data from Scottish rivers, Jackson *et al.* (2018) showed that, as a result of such features, a 1°C rise in maximum air temperature could result in maximum water temperature increases of between 0.4 and 0.7°C in summer (Figure 3.13a). In winter, the same air temperature change resulted in water temperature changes of between 0.02 and 0.36°C (Figure 3.13b). River temperatures in the north and north west of Scotland and the Cairngorm Mountains were found to be most sensitive to air temperature variation. In Wales, high confidence has been attributed to changes in population dynamics of species as a result of higher water temperatures (Natural Resources Wales, 2020b) and such changes are consistent with current observation and are likely to occur across the UK in the future.

---

<sup>23</sup> HadGEM2-ES model driven by RCP 2.6 and RCP 6.0 concentrations pathways

CCRA2 identified small, shallower lakes as being at risk from reduced circulation and larger, deeper lakes as being more sensitive to longer periods of thermal stratification reaching more deeply. International studies suggest that water temperatures are likely to increase in the future (although there are fewer published studies for the UK specifically), as a result both of increased air temperatures, as well as low flows in summer, with potentially negative impacts on sensitive species (Watts and Anderson, 2016).

### 3.12.1.2.2 Ecological effects via altered river flows and water quantity

Future alterations to flow regimes are likely to have consequences for freshwater species and habitats, as well as the water available for abstraction. Projected changes in river flows at Q95 (the flow that is exceeded by a river 95% of the time) are of the order of a 0% to 20% reduction across the UK by the mid-century in a pathway to approximately 2°C global warming by the late century<sup>24</sup>, except in the western highlands in Scotland, where flows increase (HR Wallingford, 2020). In a scenario of 4°C global warming in the late century, there is up to a 30% flow reduction in some areas, such as Wales, the Severn and Tweed river basins. Projected changes in river flows at Q95

<sup>24</sup> The HR Wallingford (2020) method defined the 2°C and 4°C pathways as the global warming levels (GWLs) reached late century (2070-2099) at the 50<sup>th</sup> percentiles of the UKCP18 probabilistic projections with the RCP2.6 and RCP8.5: 1.8°C and 4.2°C respectively. The former is near the centre of the lower CCRA3 scenario, and the latter is on the upper bound of the CCRA3 higher scenario (see Chapter 2: Watkiss and Betts, 2021). Late-century regional climate states were taken from the UKCP18 perturbed-parameter ensemble (PPE) of global 60km projections at those GWLs. Mid-century climate states were taken from the 60km PPE at the GWLs reached with RCP2.6 and RCP85 50<sup>th</sup> percentiles in 2040-2069. See HR Wallingford (2020) for details.

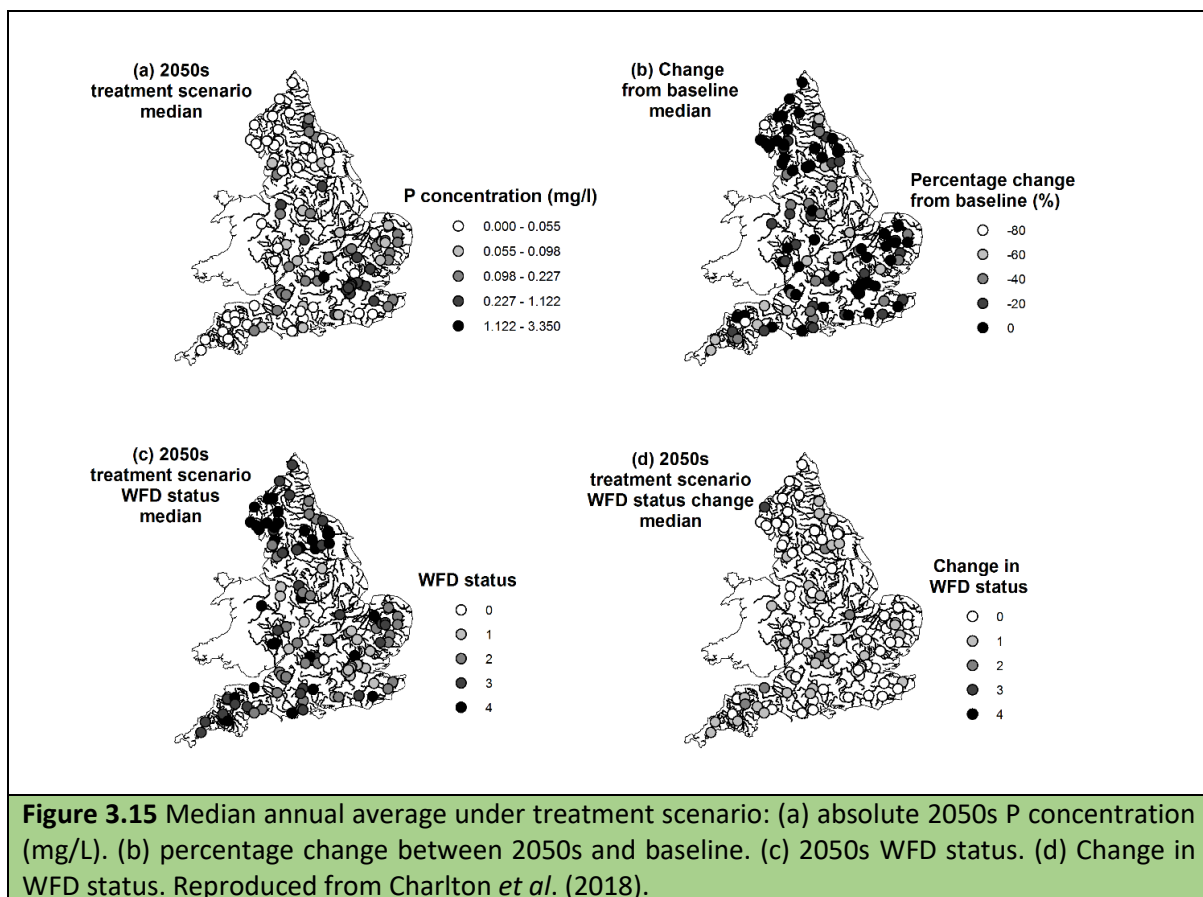

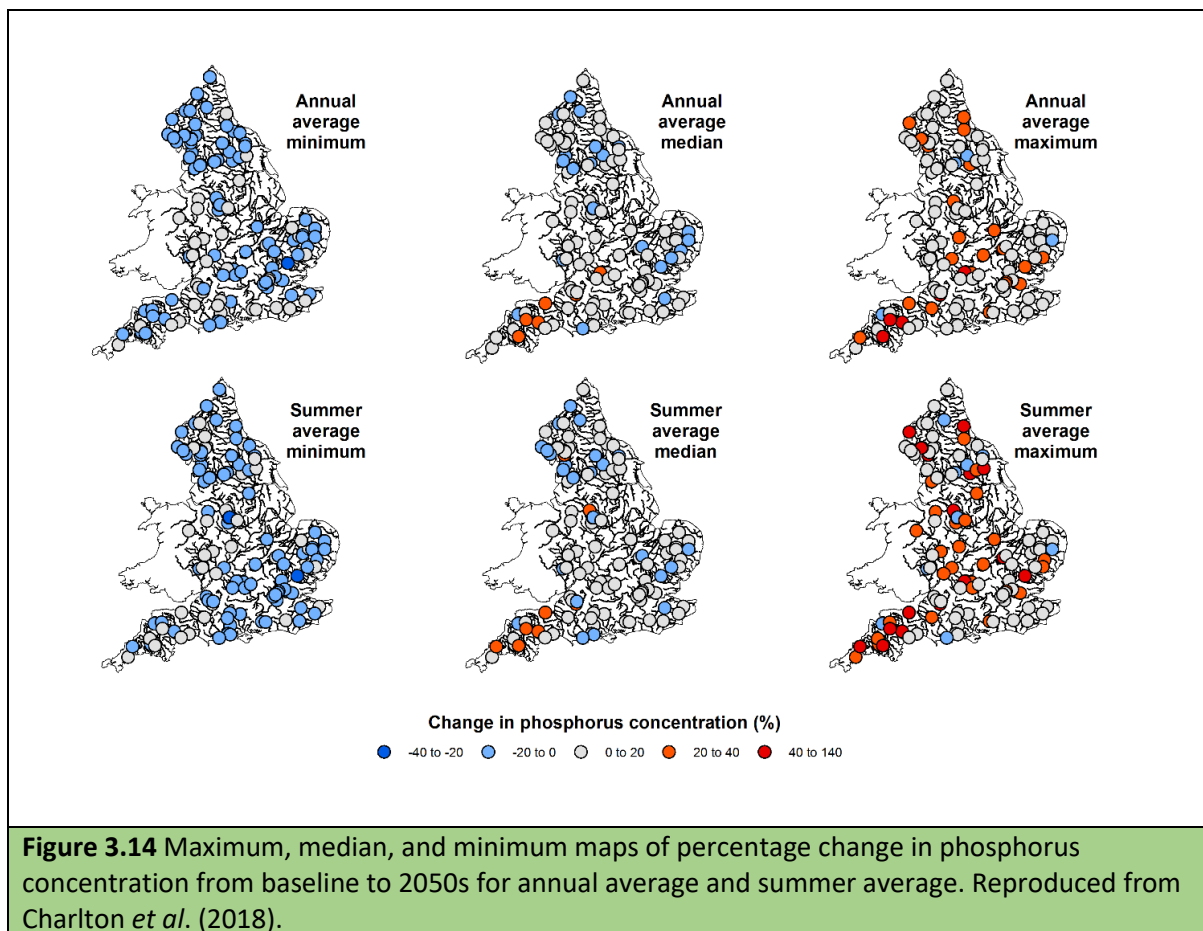

across the UK are of the order of 0% to 50% reduction by the late-century in the 4°C warming scenario.

Modelling based upon a combination of future climate change and socio-economic scenarios, suggests that over 50% of the European river network could change eco-hydrological type (i.e., ecologically relevant flow regime, defined by features of average flow and flow variability) by mid-century (Laize *et al.*, 2017). Indeed, it is projected that novel eco-hydrological river types may occur in some regions in future (9% to 18% of the river network), with the potential to support novel ecosystems.

While low flows are important in leading to possible loss of river connectivity, reduced nutrient dilution (section 3.12.1.2.3), and changes in freshwater biodiversity (section 3.12.1.1.2), in our view it is probably drought in a sequence of weather events (e.g., dry winter and then summer drought) that will have more significant impacts. Following drought, many species will recover, but there are possibilities of local losses or replacement by other species during recovery.

### 3.12.1.2.3 Water quality

Climate change could potentially cause water quality deterioration in rivers, because reductions in future flows could also reduce dilution of phosphorus inputs from wastewater treatment works, and lower the rate at which phosphorus is flushed from river reaches (EA, 2019). This, along with rising summer water temperatures, could stimulate algal growth. However, projected future changes in water quality remain highly uncertain due to the complex interaction between climate change and land use change, which will vary by catchment. Modelling of estimated in-stream total reactive phosphorus (TRP) concentrations for the 2050s under 11 climate change river flow scenarios, and under scenarios of both current and higher levels of sewage treatment in England, showed small, but spatially variable, increases in average annual TRP, with higher changes in summer (Figure 3.14, Charlton *et al.*, 2018, EA, 2019b). Improvements to point source sewage treatment (reductions in final effluent TRP concentrations to a maximum of 0.5 mg/L), though likely to result in lower river TRP concentrations, were found to be insufficient to improve the WFD phosphorus status for the majority rivers (Figure 3.15, see also EA 2019b), thus suggesting that sources of diffuse pollution from land use also need to be addressed.

Algal bloom risk has been modelled as a function of phosphorus concentrations, river flows, water temperature, and sunlight duration using the 11 Future Flows Hydrology (FFH) scenarios (Prudhomme *et al.*, 2013) driven by climate projections reaching 4°C global warming at the end of the century<sup>25</sup>, with a Load Apportionment Model (LAM) from UKCEH (EA, 2019c). This showed an increase in median bloom risk days from baseline (1961 to 1990) to the 2050s (2040 to 2069). The median increase was approximately eight days across 26 sites in England, from about 50 in the baseline period, although the maximum increase is up to 15 days. The change in risk is variable by the 2080s (2070 to 2098), with about 50% of sites showing reduced risk relative to the baseline period, resulting in a median increase of about 4 days and a maximum of up to 16 days. This variability is a function of flow variability, water temperature and sunlight duration, with the latter two seeming to be particularly important. The recent CCC thresholds project (Jones *et al.*, 2020) also estimates an increasing occurrence of temperatures that would stimulate algal blooms, assuming sufficient nutrient availability, across the UK (see below).

Using a model cascade, Bussi *et al.* (2016) projected likely impacts of a combination of changing climate and land management on phytoplankton concentrations in the River Thames. Specifically, the study suggests that a combination of reduced precipitation and rising air temperature in the future, coupled with increased conversion of land to intensive arable agriculture, is likely to result in increased phytoplankton (especially cyanobacteria) growth in the Thames. However, catchment-scale phosphorus mitigation strategies (reduced fertiliser application and enhanced wastewater treatment) could offset climate driven increases in phytoplankton growth.

Hydrological modelling for the Thames and Yorkshire Ouse using the CLASSIC model driven by projections of approximately 3°C and 5°C at the end of the century<sup>26</sup> suggested that by the 2080s, lower river flows in all seasons apart from winter could lead to longer residence times (by up to a month in the Thames). Nutrient, organic and biological contaminant concentrations could be elevated by 70–100% pro-rata (Johnson *et al.*, 2009) assuming sewage treatment effectiveness remains unchanged. In addition to stimulating phytoplankton growth, these changes could also result in an increased risk of human exposure to enteric pathogenic microbes, though there is considerable uncertainty regarding the magnitude of this risk, and the specific pathogens that are most likely to increase (see also Chapter 5: Kovats and Brisley, 2021).

Scenario modelling of lake ecosystems suggests that climate-driven increases in water temperature, and changes in mixing depth, can lead to increased algal growth and water quality deterioration (Gray *et al.*, 2019). However, the impacts of climate change on algal bloom magnitudes, and the dominant bloom forming species, will be mediated by important interactions with changing nutrient concentrations and cycling (Elliott *et al.*, 2016, Radbourne *et al.*, 2019) and thus by land and wastewater management.

Water quantity and quality will together influence the effects of climate change on water supply. Recent water resource modelling for the Thames catchment, under multiple climate, land-use and water demand scenarios (Mortazavi-Naeini *et al.*, 2019), projects substantially reduced water supply

---

<sup>25</sup> UKCP09 HadRM3 regional climate model perturbed-parameter ensemble with the SRES A1B scenario

<sup>26</sup> UKCIP02 probabilistic projections with the low (SRES B1) and high (SRES A1FI) scenarios

reliability by mid- and end-of-century (by up to 54% and 83%, respectively). Crucially, these projected changes result from both reduced water quantity and quality factors such as suspended solid concentrations or algal blooms.

In addition to the interacting effects of water temperature and nutrient concentrations on water quality and ecological state, there are also potential risks related to saline intrusion/coastal inundation (see also Risk N10: Risks to aquifers and agricultural land from saltwater intrusion). The magnitude of such risks is likely to be heavily dependent on local conditions, such as abstraction, hydraulic gradient, and tidal patterns (Defra, 2014). As an example, at the Bosherton Lakes SAC in west Wales, there is a low, but increasing, probability of tidal inundation from the 2050s to 2080s. Such events could greatly deteriorate features of interest on the site, specifically charophyte communities (Holman *et al.*, 2009). Such events are most likely under conditions of rising sea level, and coincident tidal surge and high tides.

#### 3.12.1.2.4 Species abundance and distribution

Aquatic macroinvertebrate communities are expected to be further affected by future climate change, since they are sensitive to water temperature, oxygen concentrations, flows, and sedimentation (Johnson *et al.*, 2009). In lowland rivers, it is suggested that a shift in composition from species typical of high to low flows is “likely” (Johnson *et al.*, 2009). In Wales, inland waters (e.g., lakes and rivers) were assessed as being highly negatively affected by hotter, drier summers (Berry, R. *et al.*, 2019), with implications for such communities. Modelling of future climate impacts on invertebrate communities within the Welsh Llyn Brianne catchment projected that warming of 1°C to 3°C could eliminate ten (mostly rare) taxa; up to 12% of the local species pool (Jones *et al.*, 2013). Using climate projection data from the rivers Thames and Ouse, Johnson *et al.* (2009) also infer “possible” future changes in the composition of submerged plant communities with rising water temperatures, lower flows, and elevated CO<sub>2</sub> concentrations in river water.

Climate change is also one of a number of possible threats to UK recreational fisheries (Winfield, 2016) with cold-water fish such as Arctic charr already showing declines at least partly related to climate change (Winfield, 2010). Conversely, warm-water species, such as the roach, are projected to expand their range across the UK (Elliott *et al.*, 2015). Whilst such range expansions may be considered an opportunity (see also Risk N13), newly arriving species can have a wide range of impacts upon recipient ecosystems. Salmonid species have limited capacity for genetic adaptation of their upper temperature tolerances with warming (Elliott and Elliott 2010), which raises concerns over the persistence of these species. Indeed, Elliott and Elliott (2010) concluded that “*If winter stream temperatures in southern Britain and Ireland continue to increase at their present rate, then they will soon exceed the lethal limit for egg development in [Atlantic salmon] and [brown trout]*”. Climate change impacts upon species such as salmonids are highly relevant to the sport fishing industry (contributing around £113 million per year to the Scottish rural economy, Scottish Government (2019)). In addition to temperature effects, Johnson *et al.* (2009) suggest that lower flows may result in elevated concentrations of contaminants that would affect sex determination and sex ratios in fish populations, and that rising temperatures could alter disease dynamics. However, the magnitude of these effects is currently uncertain.

Johnson *et al.* (2009) suggest that climate change may adversely affect riverine bird populations through changes in phenology i.e., seasonal mismatching between the timing of chick rearing and the timing of peaks in food resources. However, as noted above (Samplonius *et al.*, 2021), we currently lack sufficient evidence of such effects for many freshwater species. Modelling of changes in suitable climate for birds under the future 3°C-rise scenario projected that common scoter, Slavonian grebe, ruff, pintail and marsh warbler have a high likelihood of extinction (Ausden *et al.*, 2015; Hayhow *et al.*, 2017). In addition, an increasing frequency of extreme events (floods and droughts) could impact aquatic birds by destroying nests and altering feeding opportunities (Johnson *et al.*, 2009).

It should be noted that, under the Water Framework Directive, community composition data for some organism groups (e.g., macroinvertebrates, macrophytes, fish) have been used as indicators of ecological state. Looking ahead, though there is some uncertainty regarding our approach to fresh water regulatory monitoring post EU-exit, climate change could alter status assessments of sites by impacting upon these ecological communities.

#### 3.12.1.2.5 Socioeconomic scenarios

Using academic literature, published reports and expert opinion, the Environment Agency have developed five qualitative socio-economic scenarios (or “story-lines”) for the water environment of England and Wales, up to 2050 (EA, 2017a):

- I. Uncontrolled Demand (UD, governance is directed towards shorter term socioeconomic concerns, consumption reflects an intensified materialistic “desire economy”).
- II. Innovation (INN, governance systems and decision-making focus on longer term sustainability, consumption reflects an intensified materialistic “desire economy”).
- III. Sustainable behaviour (SB, governance systems and decision-making focus on longer term sustainability, consumption patterns are constrained with a focus on well-being and sustainability).
- IV. Local resilience (LR, governance is directed towards shorter term socioeconomic concerns, consumption patterns are constrained with a focus on well-being and sustainability).
- V. Reference (REF, a future based on a policy and governance context similar to today).

Consideration of nine indicators of significant water management issues, or exposure pressures, under these socio-economic scenarios showed how the uncontrolled demand and local resilience scenarios could lead to negative impacts on the water environment (Table 3.35) and water management challenges (Table 3.36). Innovation and sustainable actions that seek to build long-term resilience and sustainability, while having opposite patterns of consumption, could have positive or no impacts on the water environment or management challenges (Tables 3.5, 3.6). In their project summary for this work, the Environment Agency (2017b) concluded that “*scenarios that are driven by short-term growth and competitiveness could undermine the requirements of current environmental legislation and make the negative impacts of climate change worse. Conversely, scenarios that are characterised by long-term sustainability may offer substantial environmental improvements, though currently desired environmental outcomes may not be fully achieved*” (p1).

**Table 3.35.** Impacts of four socio-economic scenarios on the UK water environment (redrawn from EA, 2017a. Contains Environment Agency information © Environment Agency and database right.). UD = uncontrolled demand; INN = innovation; SB = sustainable behaviour; LR = local resilience (see text for more detail on the scenarios).

Impacts on the water environment	Scenario			
	UD	INN	SB	LR
Loss of sensitive species				
Invasion and spread of non-native species				
Acidification of soils and waters				
Toxic and sub-lethal impacts on fish and macroinvertebrates				
Obstacles to fish passage				
Detrimental impact on aquatic plants				
Dried out wetlands and ephemeral chalk streams				
Reduced water flows, lower flow velocities and reduced depth				
Alteration of natural flow variability				
Intrusion of saltwater into groundwater				

**Table 3.36.** Impacts of four socio-economic scenarios on the UK water management challenges (redrawn from EA, 2017a. Contains Environment Agency information © Environment Agency and database right.). UD = uncontrolled demand; INN = innovation; SB = sustainable behaviour; LR = local resilience (see text for more detail on the scenarios).

Water management challenges	Scenario			
	UD	INN	SB	LR
Eutrophication				
Acid and nitrogen deposition				
Un-ionised ammonia				
Nitrate in drinking water				
Microbiological contamination				
Sediments				
Chemical pollution				
Hydromorphological alterations				
Water quantity				
INNS				

### 3.12.1.3 Lock-in and thresholds (N11)

Lock in risks could come from the use of hard infrastructure for flood management preventing the adaptation of habitats, while barriers within a river could disrupt species movements.

Potential threshold temperatures have been identified for some climate impacts as part of a national climate impacts screening exercise (Jones *et al.*, 2020):

- *Temperature effects on phytoplankton blooms in lakes.* Phytoplankton blooms can impact negatively on water quality, recreation, and biodiversity. Based on the available evidence, the incidence of such blooms is likely to be greater when air temperatures exceed 17°C. At a UK scale, it is estimated that the number of months per year exceeding this temperature threshold will increase from approximately 1 under baseline (2001-2010) conditions to approximately 2 under a +2°C warming scenario, and 3 under a +4°C warming scenario. This represents a marked increase in the risk of blooms with ongoing climate change. Such blooms can have wide ranging economic impacts, including on property values, water

treatment costs, tourism and fisheries revenue. However, the costs of this risk alone for the UK, based on a single UKCP18 model variation, were projected to increase from £173 million at baseline (2001-2010) to £295 million under a 2°C scenario and £481 million under a 4°C scenario. The same study, using 28 model variants/projections from across the two families of ensembles available from UKCP18 data (PPE and CMIP5) on the trajectory towards a 4 °C world under a RCP8.5 concentrations pathway found that the figures were £329 million and £332 million, respectively, for the 2050s, and £420 million and £332 million for the 2080s.

- *Temperature effects on phytoplankton blooms in rivers:* As above, phytoplankton blooms can impact negatively on water quality, recreation, and biodiversity. Available evidence suggests that blooms in rivers are more likely when temperatures exceed 19°C (based upon Bowes *et al.*, 2016). At a UK scale, it is estimated that the number of months per year exceeding this temperature threshold will increase from <1 under baseline conditions to approximately 1 under a +2°C warming scenario, and 2 under a +4°C scenario. Additional thresholds for higher bloom risk have been identified (flows of <30 m<sup>3</sup> s<sup>-1</sup>, >20 h sunshine during previous 5 days, Bowes *et al.*, 2016) and these could be used to refine projections of bloom exceedance. There is currently insufficient evidence to place an economic value on these changes.
- *Temperature effects on fish habitat volume in lakes:* Cold water fish species, of conservation concern, are especially vulnerable to the effects of climate change. Based upon the example of the vendace (the UK's rarest freshwater fish), it is known that rising water temperatures can reduce available habitat, and that this effect is compounded by the effects of decreases in oxygen concentrations. Water temperatures above 18°C are thought to be detrimental to vendace. At a UK scale, it is estimated that the number of months per year exceeding this temperature threshold will increase from approximately one under baseline and +2°C warming scenarios, to approximately three under a +4°C warming scenario. There is currently insufficient evidence to place an economic value on these changes.
- *Temperature effects on zooplankton species composition in lakes:* Zooplankton are important microscopic grazers of algae in freshwater ecosystems and, as such, contribute to maintaining good water quality. They are also an important food resource for freshwater fish species, especially in their vulnerable young life-history stages. The composition of zooplankton communities will affect these contributions to ecosystem functioning and is sensitive to rising water temperatures, both directly and indirectly, through the impact of warming on algal growth and rates of predation. There is evidence to suggest that, above water temperatures above 14°C, community composition can change. At a UK scale, it is estimated that the number of months per year exceeding this temperature threshold will increase from approximately 3 under baseline conditions to approximately 4 under a +2°C warming scenario, and 5 under a +4°C warming scenario. There is currently insufficient evidence to place an economic value on these changes.

In addition to these examples, critical temperature thresholds have been determined for salmonid fish species which are important to commercial and sports fisheries; the Atlantic salmon, brown trout and Arctic charr (Elliott and Elliott, 2010). These thresholds vary not only among species, but also among life stages for any given species. There is, therefore, the potential for future work to screen for threshold exceedances at multiple life-history stages. However, it is important to note that there is a degree of uncertainty associated with any estimates of threshold exceedance. An

important source of such uncertainty is the fact that climate change interacts with other environmental pressures in affecting freshwater ecosystems. In the case of algal blooms, changes in nutrient loading from catchments and water treatment works, along with changes in water colour (due to organic matter content), and rates of water flow will also have very strong effects on bloom incidence and magnitude. Water bodies with high nutrient loadings, and slow-flowing rivers will be at particular risk of algal blooms. These nutrient effects on algal growth will have cascading effects on zooplankton that are already affected by temperature. Furthermore, nutrient pollution of water bodies will also affect oxygen concentrations by stimulating algal growth, placing additional constraints on cold-water fish habitat. It is likely, therefore, that climate thresholds will be dependent on other environmental factors. Further resolution of the nature of such interactions is a priority for future research.

#### 3.12.1.4 Cross-cutting risks and interdependencies? (N11)

Abstraction of water exacerbates drought effects by reducing water to support ecosystems. Following drought there may be increased concentration of fertilisers, pesticides and other chemicals. All of these factors are likely to affect water temperatures as well (Poole and Berman, 2001; Hannah and Garner, 2015), compounding the effects of climate change. Canalisation of watercourses increases flow rate and reduces water-holding capacity of catchments. Similarly, drainage of wetlands has reduced water-holding capacity.

#### 3.12.1.5 Implications of Net Zero (N11)

Inland waters are an integral part of the global carbon cycle. Lake sediments can act as a long-term carbon sink, and it has been estimated that 820 Pg of organic carbon is buried within such sediments globally (Tranvik *et al.*, 2009). As such, carbon sequestration in lakes may be considered a nature-based solution to contribute to Net Zero targets. However, carbon burial and processing within fresh waters will be affected by ecosystem state, and pressures acting upon it. There is an urgent need to understand these dependencies within the UK and the global context. If done effectively, Net Zero could decrease the magnitude of this risk through agricultural practices that optimise the efficient use of nitrogen on cropland and grassland, leading to improved water quality (see Risks N4 and N6). Afforestation and peatland restoration (see Risk N1 and N5) could also contribute to improving freshwater quality, as well as the reduction of flooding. While beyond the Net Zero Further Ambition scenario, the better use of lowland agricultural peatland (e.g., seasonal management of the water table) could have similar effects.

Freshwater habitats are increasingly hosting floating solar PV arrays across the world, to provide renewable energy and contribute to Net Zero (e.g., the array at Godley Reservoir, Greater Manchester). However, the unintended ecosystem effects, both beneficial and detrimental, of such installations are not well-understood (Armstrong *et al.*, 2020). Such fundamental research is therefore high priority.

## 3.12.1.6 Inequalities (N11)

No inequalities associated with climate change were identified in relation to risks to freshwater species and habitats.

## 3.12.1.7 Magnitude Scores (N11)

**Table 3.37** Magnitude scores for risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Northern Ireland</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)
<b>Scotland</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)
<b>Wales</b>	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	Medium (Medium confidence)	High (Medium confidence)

Notes: Magnitude categories based on the level of agreement of the evidence and expert judgement of authors (in agreement with CCRA reviewers) are medium for the present day and for future for the 2050s and for the 2080s, on a to pathway stabilising at 2°C by 2100. This means there are intermediate impacts on or loss of species groups across all four UK countries in the 2050s. However, the countries are scored as high risk for the 2080s under a trajectory of a 4°C world at the end of the century, resulting in potential major impacts on or loss of species groups.

## 3.12.2 Extent to which current adaptation will manage the risk (N11)

Research has explored how certain adaptation actions could help reduce the risk of climate change and has helped to inform adaptation. Some examples are given below.

### 3.12.2.1. Thermal refugia (N11)

The provision and preservation of thermal refugia could promote temperature heterogeneity in rivers, and thus aid the survival of cool-water species, such as salmonids, under warming conditions (Kurylyk *et al.*, 2015). For example, deep pools would allow access to deeper, cooler water under drought conditions, and the removal of obstacles could allow salmonids to access cooler inflow streams to lakes (Elliott and Elliott, 2010). Management of clear felling, ground water pumping and aggregate extraction are all options for preserving cool water refuges created by ground water inputs, and planting/preservation of riparian vegetation can shade and cool river reaches. CCRA2 noted that, in order to address the risks to freshwater species from higher water temperatures, more research is needed to refine further the strategic approach to riparian tree planting to provide cooling for sensitive water bodies with high biodiversity. New modelling (e.g., Garner *et al.*, 2017; Jackson *et al.*, 2018) and literature review (Feld *et al.*, 2018) has shown the potential for riparian woodland to decrease mean water temperatures, while forest harvesting could increase them (Millar *et al.*, 2012). Field experiments and modelling in the River Dove, Derbyshire showed that approximately 1 km of riparian shade is needed, at downstream sites, to cool rivers by 1°C in summer (Johnson and Wilby 2015). However, the shading effects of riparian vegetation are contingent on channel width, as well as the width, length and vegetative structure and composition of the riparian zone (Feld *et al.*, 2018); key considerations for mitigation of the effects of climate change via these means. In addition, monitoring of temperatures within existing thermal refugia would provide the evidence needed to preserve and enhance them (Kurylyk *et al.*, 2015).

### 3.12.2.2 Management of water quality (N11)

The impact of warming on algal blooms is synergistic with the effects of the primary stressor, nutrient loading (Rigosi *et al.*, 2014; Richardson *et al.*, 2018), which has a dominant effect on the maximum capacity of algal standing crop in lakes (Carvalho *et al.*, 2013). Therefore, adaptation that primarily focuses on nutrient management will likely reduce the size of the effect that temperature can have on algal biomass.

Nutrients could be reduced through enhanced wastewater treatment processes, which form part of various environmental programmes, such as the National Environment Programme. It is also important to reduce nutrient run-off from agriculture, for example through precision fertiliser application, or by creating buffer strips around fields and water bodies to reduce nutrient loads reaching the water. Capacity is largely available for the application of some land management techniques, which would have immediate benefits, but action depends on the incentives or regulation in place (Jones *et al.*, 2020). Rules within existing agri-environment schemes are targeted at reducing the instances of nutrient run off. In addition, there are relevant policy instruments (see below).

Additional measures, such as in-lake interventions to minimise bloom risk (e.g., chemical remediation, manipulating flushing rates, mixing and aeration, biomanipulation, and shading water columns with floating solar panels), are not widely practiced at present. Therefore, Jones *et al.* (2020) considered the impact of current levels of adaptation on mitigating risks to be low.

In summary, the implementation and improvement of nutrient management practices, to reduce nutrient loading to watercourses, will have immediate benefits. It is likely, however, that further adaptation through land use change (buffer strips, afforestation etc.) may be required to maximise these benefits. Combining these land management changes with water management practices (e.g., chemical nutrient management, mixing and aeration) may allow us to delay exceedance of water quality thresholds. Early action will reduce the risk of lock-in; therefore, timely action is important.

#### 3.12.2.3 Management for sensitive freshwater fish (N11)

Current adaptation measures focusing on catchment-wide management of nitrogen, phosphorus, or reduction in internal nutrient cycling, could be of benefit to rare species, through a reduction in eutrophication and corresponding oxygen depletion. Such measures could also lessen suspended sediment loading to water bodies, and thus siltation of important spawning grounds. As above, these measures would need to be applied more widely to have a significant impact (Jones *et al.*, 2020). Provision of artificial spawning substrates may also help offset the siltation of spawning grounds, and the translocation of eggs and larvae can be used to establish refuge populations in high-quality sites. To our knowledge, these approaches are also not widely applied. Therefore, the impact of current levels of adaptation is thought to be low.

#### 3.12.2.4 Effects of current adaptation policy and commitments on current and future risk (N11)

At the UK level, there is uncertainty about water regulations post-EU-exit and the fate of River Basin Management Plans (RBMPs) post-EU-exit is not clear at the time of writing. The form of EU-exit will affect whether the WFD still applies to the UK, although post-EU-exit, the Scottish government is committed to maintaining water-related regulations. In Northern Ireland, the WFD requires the Republic of Ireland to establish appropriate coordination of transboundary river basins. Defra's 25YEP's targets on water quality could help ensure the good ecological status of water if they are met.

##### 3.12.2.4.1 England

##### 3.12.2.4.1.1 Management of water quality

Water Resource and RBMPs, and WFD actions, are all contributing to reducing other sources of harm in freshwater ecosystems and therefore improving their resilience. The WFD has been important in the environmental regulation of water, ensuring the reporting of the status of fresh water, the setting up of river basin districts and production of RBMPs. The RBMPs are important in formulating adaptation plans for freshwater habitats in England and they consider the impact of reduced water availability as a result of climate change, contain clear outcomes and align to the goals for freshwater habitats outlined in the 25YEP (CCC, 2019b). The Environment Agency is considering what adaptation is needed to 2°C and 4°C degree global temperature scenarios as part of its revisions to the RBMPs, to be published in 2021. The Plans outline required actions to bring freshwater habitats to good ecological status by 2021 or, where this is not possible, by 2027. The Water Industry National Environment Programme is a database of actions for water companies in England, requested by the Environment Agency, which will need to be completed to meet their

environmental obligations. It includes initiatives to tackle sewage discharge (CCC, 2019b), with a view to reducing eutrophication risk and improving water quality. Furthermore, the Environment Agency and Natural England together administer the Water Environment Grant Scheme to improve the water environment.

The Reduction and Prevention of Agricultural Diffuse Pollution Regulations (<https://www.legislation.gov.uk/uksi/2018/151/contents/made>), which include provisions for managing runoff from agriculture, came into force in England in 2018. Current catchment-wide adaptation measures are applied locally, for example in nitrate vulnerable zones, but not widely elsewhere.

#### 3.12.2.4.1.2 Management of water quantity

The Water Industry National Environment Programme is aiming to update ten abstraction licensing strategies by 2021 and all remaining strategies by 2027 to capture agreed solutions to environmental pressures in catchments. These could include solutions to flow issues related to climate change. However, the CCC stated in its last progress report that 'It is not clear how the programme considers the potential impacts of future climate change on freshwater habitats' (CCC, 2019b).

Several of the 25YEP indicators are concerned with water quality and could contribute to measuring adaptation. These include indicators on the state of the water environment and water quality, and water bodies achieving sustainable abstraction criteria. River flows and groundwater levels are sustainable when they support ecology that is only slightly impacted by human activity. Natural functions of water and wetland ecosystems will track changes in the naturalness of ecosystems functioning at the catchment scale, including restoring natural functions contributing to enhancing ecosystem services, such as biodiversity, water purification, flow regulation and resilience to climate change and the health of freshwaters assessed through fish stocks.

Some of the public goods identified as being eligible for financial assistance under the new Environmental Land Management Scheme (e.g., clean and plentiful water) may also contribute to adaptation, as could natural flood management schemes, which are encouraged and supported in National Flood and Coastal Erosion Risk Management (FCERM) Strategies in England and Wales.

Indirectly, natural flood management (e.g., Working with Natural Processes Evidence Directory, EA, 2018b) as a means of addressing flood risks could lead to multiple benefits for freshwater habitats and species, which could reduce the impacts of climate change and assist their adaptation.

#### 3.12.2.4.1.3 Thermal refugia

The 'Keeping Rivers Cool' project in England and Wales (2012-2016), led by the Environment Agency, involved measures to address the risks of warming waters in rivers. For example, it has produced guidance for developing riparian shade for species at risk, with the trees planted also contributing to mitigation (Woodland Trust, 2016). Maps based on this initiative are still being updated and there

remains a need to account for the impacts of water temperature (and reductions in water level) in monitoring and reporting on the ecological state of UK freshwaters.

#### 3.12.2.4.2 Northern Ireland

The Northern Ireland Climate Change Adaptation Programme 2019-2024 (DAERA, 2019a) states that River Basin Management Planning, to meet the targets of the Water Framework Directive, takes account of findings from the latest Climate Change Risk Assessment. Programmes of measures within these Plans are intended to address potential climate change impacts on the Northern Ireland water environment. Furthermore, the Programme promises to identify future areas for riparian planting. WFD reporting in Northern Ireland (NI) yields important data on chemical and ecological status variables that might mediate climate change impacts (DAERA, 2018a). In 2018, 31.3% of NI river water bodies were classified as 'good' status or better. In 2018, nitrate concentrations were monitored at 54 groundwater sites across NI giving an average concentration of 6.14 mg NO<sub>3</sub>/l. At 51 of the 54 groundwater monitoring stations (94%) in 2018, groundwater nitrate concentrations were consistently below 25 mg NO<sub>3</sub>/l. The Groundwater Daughter Directive (2006/118/EC) sets the groundwater quality standard at 50 mg NO<sub>3</sub>/l.

From Northern Ireland's 450 river catchments, there is a desire to see 60 - 80 catchments targeted with the necessary equipment to monitor water quality on an hourly basis, similar to the work undertaken by Teagasc as part of their Agricultural Catchments Programme (DAERA, 2018b).

#### 3.12.2.4.3 Scotland

The Scottish Government (2019) have published their second climate change adaptation programme (Climate Ready Scotland 2019-2024), which includes measures and policies that are relevant to fresh waters:

- A view that the beaver (protected by European law since May 2019) should be allowed to expand its range naturally, since their role as 'ecosystem engineers' could contribute assist ecosystem adaptation to climate change, via wetland habitat creation, and enhancing both habitat and biodiversity. They can also alleviate flooding, improve water quality and bring socio-economic benefits. A Management Framework for Beavers in Scotland has been published on the NatureScot website. There has also been incorporation of 'climate change thinking' into RBMPs, and associated measures to act on flood risk, drought, and impacted ecosystem services. There are two RBMPs: one covering the Scotland River Basin District; and the other cross border for the Solway Tweed River Basin District. There are recognitions that climate change will increasingly affect the magnitude and sustainability of water demand, land use and non-native species spread. Over the period to 2027, work will be undertaken to improve understanding of climate change impacts, and improvement measures will be considered through the lens of preparing Scotland for a future climate.
- Funding and support for projects that work with natural processes to manage flood risk, ecosystem status, and ecosystem services. An example is the Eddleston Water Project (<https://tweedforum.org/our-work/projects/the-eddlestone-water-project/>), managed by the Tweed Forum, monitoring the impacts of wetlands, woodlands, ponds and leaky barriers on

flood risk. The overarching goal of the project is to assess the benefits of working with natural catchment processes to help manage flood risk and river status.

- Creation of a Water Environment Fund, to ease pressures on imperilled species, such as the Atlantic salmon (Scottish Government, 2020a). Salmonids are of great importance to the sport fishing industry (contributing around £113 million per year to the Scottish rural economy).

Managing the quality of runoff from agriculture is regulated led by both the Water Environment (Diffuse Pollution) Regulations and Water Environment (Controlled Activities) Regulations in Scotland in 2008 and 2011, respectively.

#### 3.12.2.4.4 Wales

Wales' latest adaptation plan, "Prosperity for All: A Climate Conscious Wales" (Welsh Government, 2019b), includes actions to maintain, enhance and restore floodplains and hydrogeological systems, to reduce flood risk and improve water quality and quantity. The plan includes sub-actions that will utilise the evidence base and collaborations being developed through Area Statements to deliver targeted interventions in catchments. The adaptation plan also promotes good environmental, agricultural practice to increase the resilience of soils and water, which includes good soils and nutrient management plans.

Under Wales' Natural Resources Policy, Natural Resources Wales has developed seven Area Statements which outline the key challenges being faced by each locality, and how authorities can better manage natural resources for the benefit of future generations. The importance of resilient water quality and quantity is important in all such Area Statements. 'Working with Water' is a key theme for the South Central Wales Area Statement<sup>27</sup> and it aims to support climate change mitigation and adaptation. Similarly, a key theme to the North East Wales Area Statement (<https://naturalresources.wales/about-us/area-statements/north-east-wales-area-statement/?lang=en>) is 'Protecting water and soil through farming and sustainable land management'. It highlights the secondary benefits of sustainable farming to water, for example by providing cleaner water for biodiversity enhancement and to develop resilient ecological networks. The River Clwyd and River Dee catchments are of particular interest in this Area Statement, with concerns for water quality worsened by climate impacts. The Area Statement therefore seeks to promote nutrient reduction, create environmental benefits and nurture successful relationships between stakeholders and communities.

Also, under Wales's Natural Resources Policy, the Second State of Natural Resources Report (SoNaRR2), the register of key pressures and opportunities for freshwater (Natural Resources Wales, 2020b) identifies a number of opportunities for action including protecting and restoring freshwater ecosystems, restoring floodplain connectivity and floodplain wetland habitats at a landscape scale, significantly increasing the number and quality of lowland ponds and develop integrated river-floodplain management plans that integrate land use planning, biodiversity and flood management.

---

<sup>27</sup> <https://naturalresources.wales/about-us/area-statements/south-central-wales-area-statement/?lang=en>

SoNaRR2 (Natural Resources Wales, 2020b) views the planting of riparian corridors to help offset future temperature rises and control soil/nutrient loss in storm events as contributing to the aim of resilient freshwater ecosystems. The 'Keeping Rivers' Cool' project mentioned above applies to Wales as well as England.

As with England, Water Resources Management Plans and RBMPs are already contributing to the reduction of harm to freshwater resilience. Welsh Water's Water Resources Management Plan (Welsh Water, 2019) considers how climate change, including drought, will impact both water quantity and quality. Usage efficiency is seen as a way of lowering environmental impacts, while for water quality a catchment management approach is being adopted to manage drinking water, which will involve maintaining or improving the state of freshwater ecosystems. Making Time for Nature (Welsh Water, 2020) sets out Welsh Water's Plans for maintain and enhancing biodiversity. It contains a number of commitments, such as the better management of pesticides, contaminants and wastewater that will help improve water quantity, as well as research into why inland water bodies are failing to achieve good ecological status and the impacts of climate change.

The Welsh Water 2050 vision (Welsh Water, 2018) also seeks to promote biodiversity and ecosystem resilience, for example through managing wastewater to ensure water achieves good environmental status.

#### 3.12.2.5 Effects of non-Government adaptation (N11)

Water companies as part of a green recovery from COVID-19 are being encouraged by the government to consider greater use of nature-based solutions and to look for innovative ideas for the future that could include: water resources, flood mitigation, Net Zero or water quality improvements (Pow et al., 2020). Furthermore, water companies are due to publish Drainage and Wastewater Management Plans (DWMPs) in 2022, in order to address issues of water quality and higher flows (Atkins, 2019).

#### 3.12.2.6 Barriers preventing adaptation (N11)

There is poor evidence available about the barriers to adaptation for freshwater species and habitats. Uncertainty around EU-exit and future water regulations may be a short-term constraint. The financing of RBMPs and other initiatives for the improvement of water quality is a possible ongoing constraint, as is the enhanced monitoring for water quality, but further research is needed in this area.

#### 3.12.2.7 Adaptation shortfall (N11)

While there have been developments in strategy across all the UK's administrations to address risks to freshwater habitats and species, the focus is primarily on the impact of reduced water availability and there is less evidence of adaptation actions to address risks from high water temperatures, as well as the impacts that any actions are having and how these actions will fit within the UK-wide successors to the Water Framework Directive and RBMPs. Current actions, therefore, are thought to be insufficient to manage the future levels of risks down to low magnitude levels by the end of the

century with climate change, though confidence in this assessment is considered low due to the lack of evidence available.

### 3.12.2.8 Adaptation Scores (N11)

**Table 3.38** Adaptation scores for risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts

Are the risks going to be managed in the future?			
England	Northern Ireland	Scotland	Wales
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.12.3 Benefits of further adaptation action in the next five years (N11)

A clear mechanism that accounts for the consequences of higher water temperature and drying up of water bodies in meeting the WFD targets (and whatever their successors will be across the UK) is still needed. In England, it has been suggested that there needs to be consideration of the 'right' enabling environment (regulatory framework) that would be required to ensure a well-adapted water sector (CCC, 2019c). New environmental land management schemes in the UK post-EU-exit are likely to include measures to reduce diffuse nutrient pollution. However, such adaptation options need to be clearly built into design and piloting.

The effectiveness of a range of sustainable measures to increase ecological resilience through enhancing riparian habitat, providing a more heterogeneous channel bed morphology or creating a range of refugia for freshwater organisms during low flows has been modelled (EA, 2016). The results can point to future possible adaptation measures. It was found that assisted natural recovery was successful in restoring hydromorphological processes, thus enhancing ecological resilience, and could be effective in wandering rivers (which alternate between single-channel and braided reaches). Weir removal could have a similar effect on processes and help in restoring longitudinal connectivity. This could also be achieved through reconnecting channels in active river systems. However, flood embankment removal in wandering rivers did not increase habitat provision under low flow conditions and re-meandering and increasing channel length within low energy systems is unlikely to increase ecological resilience under low flows, but is likely to be more effective in active channels. Natural recovery also was modelled as providing greater habitat quantity and quality than the control reach for brown trout in the River Wharfe, refugia might also be increased, but habitat quality could be slightly lower (EA, 2016). It has also been suggested that small, upstream waterbodies should be especially targeted for management, given their connectivity to the wider catchment, and therefore the potential for downstream effects of stressors acting in these ecosystems (Riley *et al.*, 2018).

### 3.12.3.1 Indicative costs and benefits of additional adaptation (N11)

There is information in general on the costs and benefits of RBMPs for England's water environment, as published in the Impact Assessment (Defra, 2015), which include the options discussed in the section above, i.e., on possible options that might have high relevance for addressing increasing climate related risks. There is also some information published by the EA (2019d) as part of consultation, which highlights the need for an adaptive management approach to enhance the resilience of RBM plans. Similar information covering other parts of the UK has not been identified as yet.

### 3.12.3.2 Overall urgency scores (N11)

**Table 3.39** Urgency scores for risks to freshwater species and habitats from changing climatic conditions and extreme events, including higher water temperatures, flooding, water scarcity and phenological shifts.

Country	England	Northern Ireland	Scotland	Wales
Urgency score	More action needed	More action needed	More action needed	More action needed
Confidence	Medium	Medium	Medium	Medium

There is incomplete knowledge of climate impacts on freshwater habitats and species at present, as well as a current shortfall in adaptation measures created by a lack of evidence for specific actions to help in managing water temperatures in particular and their effects on risk reduction. The risk has therefore been scored as 'More action needed' across the UK, with further investigation also required on the scale of risk and effectiveness of these measures.

### 3.12.4 Looking ahead (N11)

A review of climate change impacts on the water environment in England (Defra, 2014) concluded that our understanding of the interactions between climate change and other stressors is currently incomplete, causing uncertainty in projected outcomes. Although this is an England-specific review, our view is that it also applies across the UK. To address this knowledge gap, there is a need to prioritise research on the responses of freshwater habitats and species to climate change in conjunction with other pressures and to highlight the implications for meeting water management objectives. In addition, there is a need to develop policy-relevant indicators of climate change impacts on freshwaters and to continue investment in the UK's long-term research capability, which enables us to detect ongoing and emerging impacts with reference to baseline/historic variation. This will allow us to better constrain environmental models that are capable of projecting future change.

### 3.13. Risks to freshwater species and habitats from pests, pathogens and invasive species (N12)

- Climate change is likely to affect pests, pathogens and INNS through changed thermal regimes, with impacts on the distribution and spread of various diseases and INNS, the rate at which invaders competitively displace native species, or through increased competition for food.
- The current and future risk is assessed as medium for Northern Ireland, Scotland and Wales, and high for England, due to the greater likely increase in the number of pests, pathogens and INNS.
- The likelihood of increased arrivals of pests, pathogens and INNS to the UK in the future, and the potential role of climate change in facilitating their establishment and spread, means more action is needed, particularly to improve capacity for rapid detection.

#### Introduction

No specific risks to freshwater species and habitats from pests and pathogens were identified in this assessment and there are currently no notifiable freshwater plant pests and diseases in the UK (UK Plant Health Information Portal<sup>28</sup>). However, should this change, pests and pathogens could reduce the health of individual species and their habitats, thus affecting key ecosystem functions. CCRA2 did identify that invasive non-native species (INNS) could be an additional stress on freshwater ecosystems, but currently INNS are primarily a consequence of inadvertent or deliberate introductions, exacerbated by the connectivity provided by rivers and streams. Their impacts include: competition with native species, predation, introduction of disease, harmless airborne pathogens becoming more virulent as the result of hybridising with formerly benign native microbes, hybridisation with native species, habitat alteration, which can lead to increased river flooding and economic costs e.g. from dealing with choked waterways (Kernan, 2015; Hayhow *et al.*, 2019). Whilst there is evidence that the number of freshwater INNS is increasing slightly (e.g., SNH 2017; JNCC, 2019) and the recent warmer winters across the UK have been favourable for the survival and development of many species (see also Risk N2), there is very little evidence on the role of climate change in affecting the rate of establishment of aquatic invertebrates (Hulme, 2016).

Currently, most of the INNS are arriving from the continent as a result of anthropogenic factors and their distribution is expanding. There is less information on pests and pathogens, but some of the INNS also carry pathogens. The current and future risk for England is assessed as high, due to the greater likely increase in the number of pests, pathogens and INNS and expansion of their range. The current and future risk is assessed as medium for Northern Ireland, Scotland and Wales, as there are a number of impacts on native species and communities. There is a range of adaptation policies and actions in place, but the likelihood of increased arrivals of pests, pathogens and INNS, and the potential role of climate change in facilitating the establishment and spread of some and the benefit of rapid detection and action, means that more action is needed.

---

<sup>28</sup> <https://planthealthportal.defra.gov.uk/>

### 3.13.1 Current and future level of risk (N12)

Note: currently available evidence is not sufficient to allow us to report on the current and future level of risk for each UK country separately.

#### 3.13.1.1 Current risk (N12)

Over 130 INNS are present in freshwater in the UK, with many of them being first reported in the Thames region (Jackson and Grey, 2013; Gallardo and Aldridge, 2020). In Scotland, about two thirds of the invasive non-native species (INNS) are higher plants (i.e., excluding mosses, liverworts, fungi and diatoms) and about 13% are found in inland surface water, whilst 26% of the top 50 INNS affect freshwater (SNH, 2017). About 35% of all notified freshwater habitat features in Scotland have INNS as a pressure, which is increasing; many of these are in an unfavourable overall condition, making them more susceptible to invasion (ClimateXChange, 2018). While in Northern Ireland, seven out of the 11 widespread INNS are associated primarily with freshwater or wetland habitats.

Various modelling studies on the impacts of climate variables on the potential distribution of selected INNS showed that mean annual temperature (Kelly *et al.*, 2014) and minimum temperature of coldest month (Gallardo and Aldridge, 2013a; Kelly *et al.*, 2014; Gallardo and Aldridge, 2015) were the most important variables. Cold temperatures can prevent or restrict the establishment of warm-water species, whilst warmer temperatures can lead to range expansion and population increases (Kernan, 2015),

Some current INNS in freshwater habitats, for example signal crayfish (*Pacifastacus leniusculus*) in rivers, result from the introduction to the UK for commercial purposes, followed by species' escape or deliberate release, leading to both competition with the native white-clawed crayfish (*Austropotamobius pallipes*) and the transmission of the deadly crayfish plague, caused by the fungus *Aphanomyces astaci*. This, together with competition, has led to the decimation of the native crayfish. Climate change may play a role in the spread of the signal crayfish and increased competition. Firkins (1993) found that the signal crayfish has a temperature tolerance which is between 1.3°C and 3°C greater than that of the white-clawed crayfish, which has an upper temperature tolerance of about 28°C. The red swamp crayfish (*Procambarus clarkii*) also is found in England and is a vector of crayfish plague, which is responsible for much of the disappearance of native crayfish species (Souty-Grosset *et al.*, 2016). It has severe impacts on aquatic ecosystems, due to its rapid life cycle, dispersal capacities, burrowing activities and high population densities, and is considered an invasive.

The Chinese mitten crab (*Eriocheir sinensis*) also has been identified as modifying natural habitats and competing with or outcompeting native species (e.g., the white-clawed crayfish), as well as transmitting crayfish plague. Currently there is little information on the effect of climate on its spread.

There are also other important INNS with already established populations in the UK, for example, the killer shrimp (*Dikerogammarus villosus*) which is considered one of Europe's most damaging INNS (Gallardo *et al.*, 2012; Hayhow *et al.*, 2019). It can cause population declines of many native species, as well as preying on other shrimp species, fish larvae and eggs, thus altering ecosystems. Bioclimate modelling of this species showed that approximately 60% of Great Britain currently has

the minimum climatic suitability for its establishment (Gallardo *et al.*, 2012). This, combined with freshwater connectivity and the presence of zebra mussels (*Dreissena polymorpha*), which facilitate the dispersal of the killer shrimp, mean that it could pose a future risk. Also, the quagga mussel (*Dreissena rostriformis bugensis*) which impacts the depressed river mussel (*Pseudanodonta complanata*) and zebra mussel are highly invasive non-native freshwater mussels from the Ponto-Caspian region. They can significantly alter whole ecosystems by filtering out large quantities of nutrients and are serious biofouling risks blocking pipes, smothering boat hulls and other structures (Atkins Global, 2019; Gallardo and Aldridge, 2020).

A freshwater amphipod (*Gammarus pulex*), which is native to Europe, but invasive in Ireland, has replaced the native amphipod (*Gammarus duebeni celticus*) and negatively impacted native macroinvertebrate communities (Lavery *et al.*, 2017). It is also an intermediate host to the fish parasite (*Echinorhynchus truttae*) which can alter host behaviour to facilitate consumption by its final host brown trout. Laboratory and a microcosm experiments, showed a positive relation for *G. pulex* between temperature and maximum feeding rates. The parasite may also be increasing its feeding rate and thus there is a risk of great infection at higher temperatures (Lavery *et al.*, 2017).

Many invasive aquatic plants reproduce very quickly and outcompete native plants as a result. For example, the water fern (*Azolla filiculoides*) can form dense floating mats covering water surface and obstruct sunlight from entering the water.

Whilst the focus has been on the impact of changing temperature on pests, pathogens and INNS, it is thought that drought may make ecosystems more susceptible to invasion (Kernan, 2015). Studies of the 1976 drought in the UK suggest that the reduction of aquatic habitats led to the extensive movement of water birds, which was likely to have been an important factor in the spread of pathogens, but only one documented example is known – that of the introduction of the trematode (*Tylodelphys podicipina*) to Slapton Ley in Devon (in Morley and Lewis, 2014). The 1976 drought also affected a wide range of pathogens and host–pathogen associations, although they mostly appear to have been relatively short-lived, largely due to the heavy rainfall which broke the drought (e.g., Suppl Table 6, Morley and Lewis, 2014). Morley and Lewis (2020) have recorded the effect of drought conditions (1995-1996) on two eye fluke species from perch (*Perca fluviatilis*) and roach (*Rutilus rutilus*). They found that *Tylodelphys sp.* decreased in prevalence in roach but not perch with the onset of drought conditions, while *Diplostomum sp.* showed a decrease in both species. Thus, climate change driven drought could represent an opportunity (Risk N13). There is no evidence of the effects of low likelihood high impact events.

Climate does have a role to play in affecting the risk from pests, pathogens and INNS. However, modelling of the possible human influence on the invasion of 126 non-native freshwater birds, crustaceans, fish, molluscs and plants, found that connections with human recreational activities had a stronger effect on invasion than all other environmental (elevation and annual mean temperature) or anthropogenic predictors (e.g., urban land cover, human population density), with the exception of recording effort and also lake presence for non-native birds (Chapman *et al.*, 2020). Thus suggesting the importance of human interactions and activities in the spread of INNS, with temperature being an insignificant factor.

### 3.13.1.2 Future risk (N12)

The future role of climate change on the arrival of INNS, and possibly pests and diseases, may be low. An expert horizon scan of the likelihood of arrival, establishment/spread and impact on biodiversity of INNS found that of the top potentially most important INNS for Great Britain five (out of 30) were freshwater (Roy *et al.*, 2014a). For the island of Ireland 18 of the top 40 were freshwater species, with the signal crayfish in the top place, killer shrimp in third place and the salmon fluke (*Gyrodactylus salaris*), which can cause serious disease in salmon, trout and some other freshwater fish, in fifth place (Lucy *et al.*, 2020). It is also in the top 30 for Great Britain. Natural spread, which could be a consequence of climate change, however, was not identified as a pathway of arrival for any of them, thus indicating that climate change is not a major factor in the arrival of species.

Given increases in the number of non-native species arriving in the UK, especially in England, and the percentage becoming invasive, it is thought that the number of INNS is likely to increase and spread under climate change (Hayhow *et al.*, 2019). This is supported by experiments on management methods for the signal crayfish which found that increasing water temperatures increased the catches in traps across sites (Stebbing *et al.*, 2016). An experiment also has shown how increasing water temperatures can increase the feeding rates of the signal crayfish (Rodríguez Valido *et al.*, 2021). Climate change also is likely to alter the areas from which INNS could come, their range within the UK, the number of species and their composition (in House of Commons Environmental Audit Committee, 2019). Modelling of the 11 most important INNS as identified by water companies in the UK showed that they had the potential to increase by an average 6% and 12% with scenarios of approximately 1.5°C and 5°C global warming<sup>29</sup> respectively (Gallardo and Aldridge, 2020). Water companies at the highest risk of invasion from these species now and in the future included Cambridge Water, Anglian Water, Affinity Water and Thames Water. Northern Ireland Water, Welsh Water, South West Water and Scottish Water are likely to be least affected.

Climate change may also alter competitive relationships. Modelling of the potential suitable climate space of the zebra mussel and the depressed river mussel and signal crayfish and the white-clawed crayfish using two GCMs (CCma-CGCM and HadCM3) and two emissions scenarios (A1b and B2a) for the 2050s suggested that temperature-related variables were the most important predictors of potential future ranges, especially annual temperature and seasonality (Gallardo and Aldridge, 2013a). A combination of the four climate scenarios showed that the overlap between the two pairs of species is likely to be maintained or possibly slightly increase in the UK.

However, climate is not the only factor affecting species movements. Modelling for Great Britain and Ireland of the invasion potential of 12 aquatic INNS, using nine environmental and four socio-economic factors, found that minimum (air) temperature was the most important factor, followed by distance to ports (Gallardo and Aldridge, 2013b). The latter was particularly important for the quagga mussel, red swamp crayfish (*Procambarus clarkia*) and bloody red mysid (*Hemimysis anomala*). Suitability for the 12 species was highest in England, followed by Wales, then Ireland and lastly Scotland. South-east England was particularly suitable due to environmental factors, but also its proximity to the continent and port activity. The inclusion of the socio-economic factors led to a 6.5 fold increase in the area predicted suitable for the quagga mussel. Similarly, an analysis of the

---

<sup>29</sup> CCSM4 climate model driven with the RCP2.6 and RCP8.5 concentrations pathways

potential risks to Great Britain from 23 freshwater invaders from the Ponto-Caspian region (south-east Europe), showed that while environmental variables can explain about 60% of the distribution, the human influence index could explain a further 25% (Gallardo and Aldridge, 2015). South-east England showed the highest suitability for these species, with a band along the southern Welsh coast and around some estuaries on the Scottish east coast. Negative interactions were thought primarily to occur through predation of native species.

For Ireland, modelling of the impact of climate on 15 INNS (eight currently established, seven potentially high-risk species, which are either not currently present in Ireland or present at fewer than five sites), showed mixed species responses to projected future climate change (Kelly *et al.*, 2014; Figure 3.16). Under a scenario of approximately 4°C global warming at the end of the century, the potential suitable climate space was projected increase moderately for three species already well established in Ireland (*A. filiculoides*, *L. minuta* and *M. aquaticum*) and increase significantly for three species only occurring at one or two sites (*E. densa*, *H. verticillata* and *L. grandiflora*). While two well-established species (*E. canadensis* and *E. nuttallii*) were projected to decrease and three to show little change. However, in regional environmental niche models for Ireland, incorporating additional non-climate factors (e.g., human influence, land use and soil characteristics), land use and nutrient concentration variables had the greatest overall importance, although for water fern (*Azolla filiculoides*), climate was more important. This species is likely to benefit from increased water temperatures, whilst projected increased flooding also may promote its spread within catchments by dispersing vegetative or seed inoculum (Millane and Caffrey, 2014).

**Figure 3.16** Temporal changes in 'hot- and coldspots' of invasions in Ireland. Maps show the numbers of invasive species, shown by colours as defined in the histograms below, for (a) baseline conditions using 1950-2000 observed data, and projected climates for the (b) 2020s, (c) 2050s, and (d) 2080s, for a scenario of approximately 4°C global warming at the end of the century<sup>30</sup>. Histograms show the distributions of invasive species richness. Reproduced from Kelly *et al.* (2014).

<sup>30</sup> CSIRO MK2 climate model driven by the SRES A2 scenario

Future projections based on regional models under a high emissions scenario suggest currently unsuitable locations increasingly will become suitable and hotspots of invasion suitability will be around major cities and river systems.

It is also possible that non-native species in the UK and currently not invasive could become so. For example, the non-native pumpkinseed fish (*Lepomis gibbosus*) is currently found only in ponds south of the Thames basin and currently it is not considered invasive as populations have been slow growing. However, it is thought that with climate change, it could become invasive, as greater flooding could increase its dispersal from ponds into rivers (Fobert *et al.*, 2013). It also likely to lead to increased recruitment and survival rates, with consequent stronger competitive effects on native species for food resources.

Climate change is also one of a number of possible threats to UK recreational fisheries (Winfield, 2016), with fish, such as Arctic charr already showing declines at least partly related to climate change (Winfield, 2010).

#### 3.13.1.3 Lock-in and thresholds (N12)

Pest, pathogens and INNS are more difficult and costly to manage once they are established and therefore good biosecurity practices and monitoring is needed to enable their detection, so effective treatment can be undertaken.

The arrival of pest, pathogens and INNS is often associated with particular events, be it the arrival of a transport vehicle/vessel or favourable climatic conditions. All species have thermal tolerances, but many of these are not documented in the literature or are unknown. With the signal crayfish having a higher temperature tolerance than that of the native white-clawed crayfish, once the former has been introduced, climate change can lead to the expansion of population numbers, with potential competitive consequences for native species. At a very local scale, spread can be associated with flooding.

#### 3.13.1.4 Cross-cutting risks and interdependencies (N12)

Pests, pathogens and INNS will interact with several other risks. The interacting risks project (WSP *et al.*, 2020) identified that increased drought stress (in winter or summer) could cause changes to pest and disease distributions, which could require greater pesticide use, with impacts on waterways, water quality and freshwater species (Risk N11). For INNS, warmer seasons may make freshwater more habitable for invasive species (WSP *et al.*, 2020), which again could lead to increased pesticide usage. INNS are also likely to compete with native species (Risk N11). Plant INNS can affect the integrity of flood defence structures, impede water flow and exacerbate flooding (Risks I2 and I4), impede navigation or recreational activity and decrease aesthetics and pose problems to health (Gallardo and Aldridge, 2020).

In Great Britain, direct management costs for freshwater INNS have been estimated at £26.0 million per year (Oreska and Aldridge 2011), of which at least £4.6 million are borne by the water industry (Williams *et al.*, 2010). As these figures are only direct costs, and do not include direct damage to infrastructures and service losses resulting from infestations they are likely to be conservative. Those for Northern Ireland have been estimated at over £46.0 million (Kelly, 2014). For the UK, the direct market impacts of signal crayfish on angling have been estimated as £1.0 million and the annual

control costs as £8.8 million, while for zebra mussels, market-based damages and control costs are estimated as £18.7 million (Oreska and Aldridge 2011; Williams *et al.*, 2010). Also, it is expected that climate change will lead to more INNS and to those present expanding their range. Early intervention in an invasion is recommended as there is likely to be an exponential increase in costs of control as an invasion progresses. The economic impacts of algal blooms in lakes and rivers for the UK were estimated to be in the order of £330 million to £420 million, not including other costs, such as clearing clogged waterways, cleaning water and loss of tourism revenue due to impacts on aesthetics (Jones *et al.*, 2020).

Given the importance of humans in the introduction of INNS, then changes in trade patterns or frequency (Chapter 7: Challinor and Benton, 2021) or developments in water infrastructure that enhance connectivity could impact this risk. For example, inter-basin transfers may be an adaptation option considered as part of addressing risks to public water supply from reduced water availability (Risk N18). This could result in the transfer of INNS. In the case of water transfer from the Severn to the Thames Basin, this could lead to the spread of the quagga mussel in the Thames, which could pose a serious threat to the conservation of freshwater mussels in the river (Gallardo and Aldridge, 2018). It is not known how changing trade patterns might affect the magnitude score, but inter-basin transfers could lead to an increase.

#### 3.13.1.5 Implications of Net Zero (N12)

Freshwater pests, pathogens and INNS are unlikely to have much impact on achieving Net Zero, but the restoration or (re-)creation of wetlands could increase habitat availability for a few species.

#### 3.13.1.6 Inequalities (N12)

No inequalities associated with climate change were identified in relation to risks and opportunities freshwater species and habitats from pests, pathogens and INNS.

#### 3.13.1.7 Magnitude scores (N12)

Magnitude categories (Table 3.40) are based on some independent evidence and the expert judgement of authors (in agreement with CCRA reviewers) of high present day and, therefore, likely high magnitude impacts on species groups for England, based on a greater risk from INNS (category: 'Major impacts on or loss of species groups'). Northern Ireland, Scotland and Wales are assessed as medium (category: 'Intermediate impacts on or loss of species groups').

**Table 3.40** Magnitude score for risks to freshwater species and habitats from pests, pathogens and invasive species.

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century

<b>Wales</b>	Medium  (High confidence)	Medium  (Medium confidence)	Medium  (Medium confidence)	Medium  (Medium confidence)	Medium  (Medium confidence)

### 3.13.2 Extent to which current adaptation will manage the risk (N12)

Adaptation measures to manage pests, pathogens and INNS in freshwater are not straightforward owing to the different impacts of climate change on these and native or target species (Kernan, 2015) and the important role of other factors in affecting the species' arrival, spread and establishment. Adaptation can include the prevention of the arrival of species, their expansion once arrived and increasing the resistance of habitats to invasion through enhancing their condition. Physical, chemical and/or biological control measures have been successful in the eradication of some freshwater INNS (Hayhow *et al.*, 2019; Horrill *et al.*, 2019), although their invasion often has not been driven by climate change.

While there is successful reduction/eradication of certain INNS, for example, coypu, muskrat, African clawed toad, fathead minnow and black bullhead (Hayhow *et al.*, 2019), others species and habitats still remain a risk and with the arrival of new ones, risks are not likely to have reduced.

### 3.13.2.1 Effects of current adaptation policy and commitments on current and future risk (N12)

In the UK there is a wide range of existing biosecurity policies and commitments for managing the risks from pests, pathogens and INNS, many of which come from EU legislation. Much of the policy framework for adaptation for freshwater pest, pathogens and INNS is the same as that for terrestrial species (see Risk N2). For example, Defra, Scottish Government and Welsh Government (2015a) are working to the Great Britain Invasive Non-native Species Strategy, which covers both terrestrial and freshwater species and Northern Ireland has a similar strategy. This section, therefore, does not repeat that material, but includes any other relevant measures specific to freshwater. It is worth noting that the Great Britain Invasive Non-native Species Strategy work has continued work on eradicating priority invasive freshwater species, (such as topmouth gudgeon, water primrose, variable-leaved watermilfoil, ruddy duck and American bullfrog), as well as managing well established species, such as floating pennywort.

Monitoring is key and is carried out by a number of organisations, including water companies, as early identification and treatment is important. INNS are currently considered by the UK under the EU Water Framework Directive, as part of assessing the ecological status of water bodies, which are downgraded from high or good ecological status if they have INNS present (Boon *et al.*, 2020). This informs the UK guidance for river Special Areas of Conservation, which should have ‘No high-impact alien species established’ (JNCC, 2016). Some INNS actions also form part of current River Basin Management Plans.

Adaptation actions currently are mostly focused around dealing with the current situation, although climate change is recognised as likely to increase the issue of biosecurity. Various initiatives exist or have been set up specifically related to freshwaters.

There are also campaigns, such as Check, Clean, Dry and Be Plant Wise, which have raised the awareness of INNS with key stakeholders, anglers and boat users (GB Non-native species Secretariat, 2019), but not that of the wider public (Creative Research, 2018).

One of the main challenges in terms of managing the impact of invasive species is that, in most cases, freshwaters are impacted by multiple interacting anthropogenic stresses, from eutrophication, climate, physical alteration and atmospheric pollution among others (Kernan, 2015). Thus, addressing some of these other stresses may enhance resistance to invasion. In some cases, in order to protect native species from INNS, it may be necessary to consider moving native species to climatically suitable areas outside of their current range, which either are not suitable for the invading species or cannot be reached by it, either naturally or due to the creation of barriers (Capinha *et al.*, 2013). The creation of isolated sanctuaries or “ark sites” have been accepted for the white-clawed crayfish, which is under threat from introduced crayfish, but additional methods are likely to be necessary.

#### 3.13.2.1.1 England

England is mostly covered by more general UK/British initiatives.

### 3.13.2.1.2 Northern Ireland

Waterways Ireland, a North South Implementation Body, works with other stakeholders and boat owners to control the spread of INNS.

### 3.13.2.1.3 Scotland

In 2018, Scotland set up the four-year Scottish Invasive Species Initiative (SISI) to tackle INNS alongside rivers and water courses in northern Scotland, focusing particularly on Giant hogweed, Japanese knotweed, Himalayan balsam, American skunk cabbage, White butterbur and the American mink.

### 3.13.2.1.4 Wales

The Wales Resilient Ecological Network (WaREN) is devising a new collaborative framework to help public and private bodies and community groups to tackle the significant impacts of INNS, which will focus on 16 INNS, including swamp stonecrop or New Zealand pigmyweed (*Crassula helmsii*). Also, INNS will form a cross-cutting theme in the forthcoming Welsh State of Natural Resources Report ((Natural Resources Wales, 2020b).

### 3.13.2.2 Effects of non-Government adaptation (N12)

Some shortfall might be addressed by non-governmental adaptation, as the Wildlife Trusts and other organisations, stakeholders or the public follow governmental guidance or awareness raising campaigns (e.g., Check, Clean, Dry and Be Plant Wise), but our view is that on its own it is likely to be insufficient to address the adaptation shortfall at the UK-wide level. Also, volunteers increasingly are being used to help with monitoring and control programmes, while the general public are being encouraged to notify sightings of pests, pathogens and INNS.

### 3.13.2.3 Barriers preventing adaptation (N12)

The barriers are the similar those for Risks N2 and include:

- Research and understanding: there has been little monitoring and evaluation of the role of climate change in the risk of INNS.
- Surveillance and inspections: insufficient inspectors at potential entry points and insufficient monitoring may limit the implementation of adaptation actions. In Wales, extending surveillance to cover military and civil facilities is being considered (Welsh Government, 2019c). Also, by restricted international collaboration and access to international pest surveillance data, especially post-EU-exit.
- Funding: this may be linked to both research and to capacity building, with Governments intending to release funds for the latter (e.g., Welsh Government, 2019c; NI Invasive Species Strategy)
- Policies: the UK Government's current definition of INNS does not include species that arrive in the UK as a result of climate change (CCC, 2019b).

- Need for wide stakeholder involvement: addressing the risk requires the involvement of a wide range of stakeholders, encouraging them to mainstream biosecurity surveillance and actions into their work and sometimes cross-border co-operation.

#### 3.13.2.4 Adaptation shortfall (N12)

As is the case for the other risks in this chapter that focus on pests, pathogens and INNS, current adaptation actions to manage risks are primarily focused around dealing with the present-day situation. While some policies do recognise climate change as likely to increase the issue of biosecurity, our view is that there is still a significant adaptation gap in managing projected future risks and additional government intervention is required to bring the risk down to a low level by the 2080s (Table 3.41).

#### 3.13.2.5 Adaptation Scores (N12)

<b>Table 3.41</b> Adaptation scores for risks to freshwater species and habitats from pests, pathogens and invasive species			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

#### 3.13.3 Benefits of further adaptation action in the next five years (N12)

The risks are not likely to decrease in the next five years and, given the environmental and economic benefits of taking early action on eradicating or controlling pests, pathogens and INNS, increasing monitoring and surveillance would be beneficial (CCC, 2019b).

##### 3.13.3.1 Indicative costs and benefits of additional adaptation (N12)

As highlighted by the numbers above, once freshwater INNS become established, damage costs can be high, as can annual control costs. There is therefore an economic case for further uptake of existing adaptation measures to prevent introduction and establishment, rather than attempt to mitigate spread and address impacts. One issue is to know where to focus such efforts: Gallardo and Aldridge (2020) undertook an example to prioritise risks (using cost-effectiveness for the prioritisation) identifying eleven invasive species that are most likely to cause disruption to the abstraction and distribution of water companies in the UK under climate change. There is also general information on the costs and benefits of River Basin Management Plans for England's water environment, as published in the Impact Assessment (Defra, 2015) and these include potential options for preventing the spread of INNS. These include biosecurity measures, monitoring, enforcing legislation banning or restricting the possession, sale and release of certain species, support for further research aimed at developing effective eradication methods and rapid response

for early invasion. These actions are collectively shown to be economically efficient, i.e., benefits outweigh costs.

### 3.13.3.2 Overall Urgency Scores (N12)

**Table 3.42** Urgency scores for risks to freshwater species and habitats from pests, pathogens and invasive species.

Country	England	Northern Ireland	Scotland	Wales
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Medium	Medium	Medium	Medium

While a range of adaptation policies and actions are in place across the UK administrations, the likelihood of increased arrivals of pests, pathogens and INNS, combined with the potential role of climate change in facilitating the establishment and spread of some, and the benefit of rapid detection and action, means that more action is needed to meet current and future risk.

### 3.13.4 Looking ahead (N12)

As with terrestrial species (Risk N2) enhanced monitoring, surveillance and early response measures to manage the freshwater risks of pests, pathogens and INNS would be beneficial, with international co-operation important post EU-exit. Cross-sectoral collaboration should improve the effectiveness of adaptation actions. Further research would enhance our understanding of the role of climate change in this risk and any specific adaptation actions required.

## 3.14. Opportunities to freshwater species and habitats from new species colonisations (N13)

- Opportunities to freshwater habitats from new species colonisations can include enhanced biodiversity, which supports a range of ecosystem services, particularly cultural ones such as recreation.
- Opportunities from climate change are assessed as low for the UK and for the DAs, both currently and in the future, as there is low evidence.
- Many of the opportunities for freshwater species and habitats do not come directly from climate change, but from human activities/trade, thus they have a low magnitude score and are assessed as “sustain current action”.

## Introduction

This was not a separate risk in CCRA2 and no specific opportunities to freshwater species and habitats were identified. As with Risk N3, new species are migrating into the UK (Roy *et al.*, 2014a) and, while this is consistent with climate change, especially if they have come from the continent, it is often difficult to attribute this to climate change, with humans frequently implicated in their arrival. Given suitable habitat, it is likely that they will expand their range, although there is potential for a few to become invasive, with negative effects on native species, altering community composition and function, in which case they become a risk covered in Risk N12. Invertebrates are the dominant freshwater non-native species to have arrived in Britain, including 12 non-native crab species (Roy *et al.*, 2014b). Opportunities can also arise from native species expanding their ranges northwards. In both cases, they can enhance species richness and contribute to community adaptation to climate change, but they could also lead to the decline of existing species populations. However, other factors, such as habitat availability and food sources have an important role to play in the realisation of the opportunity posed by climate change.

The opportunities from climate change are assessed as low for the UK and for the DAs, both currently and in the future, as there is low evidence of the opportunities across taxa and climate is likely to play a smaller part in them than other anthropogenic factors. Many of the adaptation actions that are taken to combat the risk to freshwater species (Risk N11) will facilitate species realising any opportunity and thus sustain current action is recommended.

### 3.14.1 Current and future level of opportunity (N13)

Note: it has not been possible to split the evidence of current and future level of opportunity by UK country.

Opportunities for freshwater species may not only enhance biodiversity, but they can also contribute to ecosystem services, especially cultural ones, such as recreational angling and enjoyment of wildlife, with possible associated business opportunities (B7).

#### 3.14.1.1 Current opportunity (N13)

There is relatively little evidence of the opportunities for less mobile taxa, but a number of wetland birds, such as, little egret, red necked grebe, little bittern, have arrived and started breeding (Moss, 2014) and some native wetland birds are increasing in population numbers, although this can vary across countries (Frost *et al.*, 2020). Similarly, the range margins of most southern species of damselflies and dragonflies are moving northwards (Mason *et al.*, 2015). However, these changes cannot necessarily be attributed (solely) to climate change, with a study of macroinvertebrates in the UK (but excluding these odentates) finding that the long-term species recovery in rivers was primarily due to improvements in water quality in northern England (Vaughan and Ormerod, 2012). However, over periods of less than two years, changes in the invertebrate communities could be associated with discharge and temperature. Also, other factors, such as habitat loss and fragmentation and management practices may slow their spread.

Spatial climate–abundance models for north western European (Ireland, UK, France and The Netherlands) seabirds and wintering waterbirds found climate change is likely to have been a significant driver of large-scale population trends in bird assemblages (Johnston *et al.*, 2013). Summer temperature was the most important predictor variable, followed by summer precipitation and winter temperature. They suggested that the positive effect of winter temperature on wintering birds could be a consequence of improved survival, whilst negative effects could be the result of changes in prey populations. Increased temperatures are thought to have had some positive effects on other taxa. For example, for floating plant species and introduced species, it can increase their productivity leading to greater community prominence (Moss, 2014). Eurythermal fish, such as bream (*Abramis brama*), common carp (*Cyprinus carpio*), pike (*Esox lucius*), perch (*Perca fluviatilis*) and/or shad (*Alosa spp.*) appear to be responding positively to warming, as has the introduced roach (*Rutilus rutilus*) in Ireland, whose populations have been supported.

#### 3.14.1.2 Future opportunity (N13)

Future opportunities for freshwater species include arrivals, range expansion and species population increases, however analysis is currently limited. The analysis of the potential risks to Great Britain from 23 freshwater invaders from the Ponto-Caspian region (south-east Europe), showed that 14 species could affect native species more positively than negatively, with most being crustaceans that serve as prey for fish and mussels and provide habitat to other species (Gallardo and Aldridge, 2015). However, as noted in the opportunities for terrestrial species (Risk N3), while environmental variables could explain about 60% of their distribution, the human influence index could explain a further 25%.

Climate change is also likely to lead to more birds arriving and breeding in the UK (Moss, 2014), as well as changes in population numbers. For wintering waterbirds, in a UK scenario approximately consistent with 4°C global warming in the 2080s<sup>31</sup>, while there could be 58% more birds in the entire wintering waterbird assemblage in 2080, the mean population change was projected to reduce by 33% when averaged across species (Johnston *et al.*, 2013). This was due to a few species having very large projected population gains, while most declined.

Water temperature is strongly correlated with spawning success for the twaite shad (*Alosa fallax*). An investigation of populations of this species in the Afon Tywi SAC, Wales, found that annual mean temperature estimates are below the critical threshold of 17.8°C required for spawning, although inter-annual variability results in some success (Knights, 2014). However, using the UKCP09 mean temperatures and increasing them by 1°C, 2°C and 3°C per century led to marked improvements in recruitment success in two river sections and some marginal increase in others. Out of six non-native fish species established in England and Wales, the common carp is predicted to be the most positively affected by 2050 by increases in air and water temperatures (Britton *et al.*, 2010). This, combined with propagule pressure, suggest that it could become invasive with possibly severe consequences for habitat destruction, water turbidity and loss of macrophytes.

---

<sup>31</sup> 50<sup>th</sup> percentile of the UKCP09 probabilistic projections with the A1FI emissions scenario in the 2080s (Murphy *et al.*, 2009). The projected changes in annual mean UK temperatures are within the upper end of the range for 4°C global warming in the UKCP18 derived projections (Gohar *et al.*, 2018).

As with terrestrial species (Risk N3), new species colonisations driven primarily by climate change are likely to result in species from Europe arriving in southern England, but increasingly trade, especially with south east Asia, is important in the arrival of non-native species (Roy *et al.*, 2014a). Shifting trade patterns following EU-exit and a development of the Asian market could be particularly relevant. For species already present, but expanding their range or increasing their populations, the realisation of the opportunities will depend on their sensitivity to the climate changes and other driving factors. Thus, there will be geographic variations, but there is not enough evidence to be more specific.

#### 3.14.1.3 Lock-ins and thresholds (N13)

Depending on responses to risks of flooding and to water supply, greater grey infrastructure could increase the barriers for species movements in rivers and channel modification alter habitat availability.

Each species has bioclimatic constraints (e.g., Knights *et al.*, 2014), which, for opportunities for freshwater species, means that they will benefit from warmer air and/or water temperatures. The benefits are likely to increase with the higher emissions scenarios and over time, providing a critical upper threshold is not reached. Similarly, as water levels and flows are important for species, so increases in precipitation could be beneficial, with flooding aiding species spread. However higher discharge rates could be negative for non-mobile species which might be dislodged or affected by bank erosion, whilst prolonged or frequent drought could lead to the extirpation of populations.

#### 3.14.1.4 Cross-cutting risks and inter-dependencies (N13)

The key interaction is with the risk of pests, pathogens and INNS (Risk N12), as if there is a rapid growth of species populations and widespread movement, then the species should be considered an INNS. Similarly, negative effects on the health of native species would mean that the species needed to be controlled or eradicated. Flooding can provide an opportunity for species dispersal into new habitats, although as noted above, adaptation measures to address this may impact negatively on freshwater species.

Use of natural flood management (or working with natural processes) is a nature-based solution and increasingly is used as a part of overall flood risk management plans, especially to manage small peak flows (EA, 2018b). It may involve the restoration of habitats, including woodland, peatland and moorland, as well as coastal ecosystems. This could enhance habitat availability for certain species, while the effects of natural barriers in rivers compared to hard structures is unknown, it is likely that they are permeable to small organisms.

#### 3.14.1.5 Implications of Net Zero (N13)

There are unlikely to be any implications for Net Zero.

#### 3.14.1.6 Inequalities (N13)

No inequalities associated with climate change were identified in relation to opportunities to freshwater species and habitats, from new species colonisations.

## 3.14.1.7 Magnitude scores (N13)

Magnitude categories in Table 3.43 are based on expert judgement of authors (in agreement with CCRA reviewers) of low for the present day and therefore likely low magnitude impacts on species groups across all four UK countries (category: 'Minor impacts on or loss of species groups'). There is relatively little evidence available to inform assessment of this opportunity and this contributes to the lack of confidence, both now and in the future.

<b>Table 3.43</b> Magnitude scores for opportunities to freshwater species and habitats from new species colonisations					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	Low  (Low confidence)	Low  (low confidence)	Low  (low confidence)	Low  (Low confidence)	Low  (Low confidence)
<b>Northern Ireland</b>	Low  (Low confidence)	Low  (low confidence)	Low  (low confidence)	Low  (Low confidence)	Low  (Low confidence)
<b>Scotland</b>	Low  (Low confidence)	Low  (low confidence)	Low  (low confidence)	Low  (Low confidence)	Low  (Low confidence)
<b>Wales</b>	Low  (Low confidence)	Low  (low confidence)	Low  (low confidence)	Low  (Low confidence)	Low  (Low confidence)

## 3.14.2 Extent to which current adaptation will manage the opportunity (N13)

Many species will continue responding to climate change in a beneficial way without specific adaptation actions (reactive adaptation). Nevertheless, those actions implemented or proposed to enhance freshwater species at risk from climate change (see Risk N11) could also facilitate the arrival and establishment of beneficial new species, as well as benefiting existing native species. For example, Johnston *et al.* (2013) showed how the UK's SPAs could overall continue to provide protection for wintering waterbirds over the next 70 years in a scenario approximately consistent with 4°C global warming in the 2080s<sup>32</sup>, although the species at a site and assemblages could change.

<sup>32</sup> 50<sup>th</sup> percentile of the UKCP09 probabilistic projections with the A1FI emissions scenario in the 2080s (Murphy *et al.*, 2009). The projected changes in annual mean UK temperatures are within the upper end of the range for 4°C global warming in the UKCP18 derived projections (Gohar *et al.*, 2018).

To avoid repetition the adaptation measures and plans in Risk N11 are not covered here, however, it is worth noting that the opportunities are not usually taken into account, except in recognising that new species opportunities could enhance some sites or change community composition, with possible implications for site designations.

#### 3.14.2.1 Effects of current adaptation policy and commitments on current and future opportunities N(13)

The increasing interest in and use of natural flood management, e.g., by the EA (2018a), especially (for this risk) natural barriers, to manage small-scale floods may enhance opportunities for species.

#### 3.14.2.2 Effects of non-Government adaptation (N13)

No specific actions by non-Government actors were identified.

#### 3.14.2.3 Adaptation shortfall (N13)

It is not clear what additional policies may be needed to fully realise the benefits of climate change to freshwater habitats from new species colonisations. Many adaptation interventions to enhance freshwater habitats and species at risk from climate change as outlined in Risk N11 may provide support. At present, therefore, it is our view that this benefit will be realised to a certain extent in the absence of additional government intervention. However, this current assessment is based on a limited amount of evidence currently available.

#### 3.14.2.4 Adaptation Scores (N13)

<b>Table 3.44</b> Adaptation scores for opportunities to freshwater species and habitats from new species colonisations			
<b>Are the opportunities going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

#### 3.14.3 Benefits of further adaptation action in the next five years (N13)

Maintaining current adaptation as detailed in Risk N11 is in our view sufficient at the moment, unless there is a desire to promote any particular opportunities, such as the arrival of rare and/or iconic species, in which case specific actions might be needed in the next five years.

#### 3.14.3.1 Indicative costs and benefits of additional adaptation (N13)

Given the sustain current action urgency score (Table 3.45), there is no analysis of the costs and benefits of additional adaptation action.

### 3.14.3.2 Overall Urgency Scores (N13)

<b>Table 3.45</b> Urgency scores for opportunities to freshwater species and habitats from new species colonisations				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency Score</b>	Sustain current action	Sustain current action	Sustain current action	Sustain current action
<b>Confidence</b>	Low	Low	Low	Low

Because of the low current and projected magnitude for this benefit, and the view that additional intervention is not currently needed to realise it in full, this opportunity has been scored as Sustain Current Action.

### 3.14.4 Looking ahead (N13)

These opportunities are likely to continue into the future, but the actions currently being taken need to continue to include monitoring to ensure that species that are arriving do not spread disease or become invasive. They may also require an adjustment in the accepted species composition of habitats as part of conservation planning.

## 3.15. Risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures. (N14)

- Climate-related changes in UK seas have been especially marked by a warming trend, but also by a series of other shifts in the marine environment.
- Risk magnitude for this topic is projected to increase from medium at present to high in the future, although with notable uncertainties, and there is high potential for significant thresholds to be crossed causing irreversible changes.
- There is good evidence to suggest major changes will occur to the marine environment under scenarios of both 2°C and 4°C global warming by 2100, but it is very difficult to be precise on specific details due to multiple risk factors and the interconnectivity of marine ecosystems.
- In addition to temperature rises, risks are further compounded by expected changes in ocean acidification, stratification, oxygenation, salinity, and ocean currents. If CO<sub>2</sub> concentrations reached 940 parts per million (ppm) in 2100, either through emissions higher than consistent with current policies or less extreme emissions with strong climate-carbon

cycle feedbacks<sup>33</sup>, this would probably imply a reduction in pH of 0.3 or more. This would have major implications for many marine organisms.

- Current policy lacks detailed actions that include specific outcomes for the marine sector and plans for progress reporting that recognise the scale of climate change risks.
- More action is needed now to both manage existing risks and to better prepare for the scale of future change, such as for example, a stronger role and improved safeguarding for Marine Protected Areas.
- Changes in fisheries policy, international trade and access to markets resulting from the UK's departure from the UK will likely have major implications for this topic.

## Introduction

Marine ecosystems are impacted by climate change through both direct and indirect effects on the distribution and abundance of species groups, including plankton, shellfish, fin-fish, marine birds (seabirds and waterbirds), and marine mammals. In addition, negative impacts on priority habitats of high biodiversity value may occur, as through changes in either dominant or keystone species that have a vital role in habitat formation, or on the changing relationships between species and between species groups. This risk topic covers all negative impacts from climate change for the marine environment below the intertidal zone (the latter is covered under coastal environments: Risk N17) except for pests, pathogens, and INNS, which are separately assessed in Risk N16. As an island nation, the UK has a rich and distinctive marine environment with internationally significant biodiversity and ecosystem services, notably fisheries, that contribute to its economic and social wellbeing. The UK marine fishing industry was worth ca. £1.5 billion in 2017 (total catches were worth £980.1 million) and employed 23,000 people, although this is rather unevenly distributed between sectors and around the UK, mainly a few large ports, although small inshore fisheries also support local livelihoods and culture (Parliamentary Office of Science & Technology, 2019).

This topic area is one of the largest in the CCRA and when aggregated across the many contributing risk factors we consider that the evidence now indicates that more action is required. The magnitude of risk increases from medium at present to high in future, although with notable uncertainties because of the complexity of the environment and its response to multiple stresses. Nevertheless, we have good confidence in identifying that major changes will occur to the marine environment even if the details are less certain, and that these changes will be much more disruptive at higher magnitudes of climate change (therefore much higher in a 4°C warming scenario compared to 2°C), although significant changes at lower magnitudes are also inevitable and becoming increasingly apparent even at present. Hence, more action needs to be taken now to better prepare for these changes, and indeed as change is already occurring, these actions are very likely to have short-term as well as long-term benefits, both for biodiversity and ecosystem services including fisheries.

It is very likely that EU-exit will have major implications for this topic, most notably in terms of changes in fisheries policy (quota arrangements, regulations etc.) and the impact of any changes to

---

<sup>33</sup> RCP8.5 concentrations pathway, which would either require CO<sub>2</sub> emissions above those consistent with current policies (see Introduction chapter: Betts and Brown, 2021) or a lower emissions scenario accompanied by strong climate-carbon cycle feedbacks (see Chapter 1: Slingo, 2021)

international trade and markets. At present though, finalised details on post-EU-exit arrangements are yet to be made. Similarly, any implications arising from the COVID-19 pandemic remain only speculative rather than sourced by evidence, although it is quite likely that some monitoring activities will have been adversely affected.

### 3.15.1 Current and future level of risk (N14)

#### 3.15.1.1 Current risk (N14)

Mean annual sea temperatures in UK waters have shown a consistent warming trend from the 1970s onwards superimposed on shorter-term fluctuations, with coastal sea surface temperatures now 0.6°C warmer in the most recent decade compared to the 1961–1990 average (Tinker *et al.*, 2020). In addition to these longer-term trends, changes in the mean climatological state of the North Atlantic Oscillation (NAO) have also led to changes in water current strength and circulation in the North Atlantic.

Accompanying this general warming trend have been more complex variations in salinity as the circulation of the Atlantic and shelf seas adjusts over multiple timescales. Hence, the salinity of surface waters to the north and west of the UK had increased since the 1970s until a more recent decline from about 2012, whilst deep water salinity in this region had freshened to about 2000 and then generally remained more stable (Dye *et al.*, 2020). By contrast, salinity of UK shelf seas shows no clear long-term trends that emerge from a pattern of considerable annual and decadal variability (excepting possibly more significant variation in the northern North Sea). On a shorter timescale, observational evidence clearly shows an extreme freshening event (unprecedented for 50 years) occurred in the subpolar eastern North Atlantic, west of the UK, from 2012 to 2016. Analysis has indicated that this freshening event was a distinctive feature of the eastern subpolar gyre and its interactions with adjacent circulation systems, caused by unusual winter wind patterns driving major changes in ocean circulation, including slowing of the North Atlantic Current and diversion of Arctic freshwater from the western boundary into the eastern basins (Holliday *et al.*, 2020). The relevance of these shorter-term variations, in addition to the long-term trends, is that the diversion of nutrient-rich and oxygen-rich subpolar waters into deeper troughs and basins (including the Rockall Trough etc.) can stimulate ecosystem productivity, at least temporarily, providing a distinct contrast to the incursion of warmer waters.

Previous CCRAAs have extensively evaluated the role of acidification caused by the oceanic uptake of CO<sub>2</sub>. Although average global acidification has increased by about 26% since pre-industrial time, present indications are that the reduction of pH has been more rapid in UK waters compared to the whole North Atlantic for which ocean surface measurements indicate a reduction in pH between 1995 and 2013 of 0.0013 units per year (Humphreys *et al.*, 2020). The ecological effects of acidification have been primarily inferred from experimental studies, either through reduced availability of calcite in shell-forming species or aragonite in corals, molluscs and algae. Maerl beds are also vulnerable to changes in pH which affects skeleton formation in addition to the impact of temperature on growth and reproduction. In addition, lowered pH has been found to depress feeding activity in deep-sea demosponges and increase foraging times of deep-sea echinoids.

Warming also means that seasonal stratification, which acts to limit mixing of shallow warmer waters and deeper cooler waters, is occurring earlier on average and lasting longer, although there are no clear long-term trends in strengthening of stratification (Sharples *et al.*, 2020). Changes in stratification have implications for plankton growth rates, species composition and distribution, hence affecting other species that depend on plankton, and may also potentially affect algal blooms.

Dissolved oxygen concentrations are also declining as a result of a decrease in the solubility of oxygen and increase in stratification frequency to that extent that some UK waters have been identified as oxygen deficient in late summer (although not hypoxic as with other European shelf seas) (Mahaffey *et al.*, 2020). Decreased oxygen concentrations and saturation may also be related to both physical processes and an increase in oxygen utilisation in the marine environment.

Studies of marine biological responses continue to show a very strong relationship with warming, including poleward shifts in species distributions across a wide range of taxa, changes in species phenology, and increased abundance of warm water species while cold water species decline (Poloczanka *et al.*, 2013; Genner *et al.*, 2017; Hastings *et al.*, 2020). Evidence is also available to indicate that species movements appear to be insufficient regarding the rate of climate change. In the North Sea, a recent study of benthic invertebrates has reported that their ranges would need to shift latitudinally by 8 km/yr to keep up with climate change, but populations are currently moving at a lesser rate of 4-7 km per year (Hiddink *et al.*, 2014). Changes in migratory patterns have also been detected, especially when linked to warmer winter temperatures.

For some species groups, the interaction of warming with other drivers noted above (salinity, acidification, stratification, oxygenation) is linked to further distinctive ecosystem relationships, although distinguishing multiple factors can be difficult, as discussed further below. In addition, other pressures are also continuing to have a detrimental effect on many species, notably overfishing and pollution, both in UK waters and internationally (State of Nature Partnership, 2019; IPBES, 2019; Moffat *et al.*, 2020). Climate change may also be interacting with fisheries pressures to further modify ecosystem relationships. For example, in the North Sea the expanded range and increased abundance of squid is considered likely to be a combination of warming effects and opportunistic adaptation due to declining fish populations, as has been also suggested for jellyfish abundance (van der Kooij *et al.*, 2016).

Harmful Algal Blooms (HABs) and associated eutrophication can also have negative effects on marine biodiversity, by depleting oxygen and reducing overall water quality. Although temperature is a key driver, the impact of climate change on HABs is complex due to the irregular influence of extreme weather events and nutrient runoff pollution from land, in addition to the potential influence of large-scale ocean currents (Wells *et al.*, 2015). In recent years, the areas most affected include the south-eastern North Sea, west coast of Scotland and Northern isles, and some coastal waters of the Celtic Seas, although monitoring is often linked to risk management reporting for shellfish and aquaculture activities (Bresnan *et al.*, 2020). Pollutant runoff and associated turbidity, both of which may be affected by increased heavy rainfall events, can also affect shallow-water seagrass habitats which have high biodiversity and ecosystem service value.

As highlighted in CCRA2, climate sensitivity is generally most evident at lower trophic levels, notably in marine plankton, but is typically more difficult to attribute with high confidence at higher trophic

levels due to the potential for multiple additional factors influencing species response. Plankton communities can show rapid responses to changes in nutrients, salinity, and temperatures, with changes in abundance varying regionally and by group for both phytoplankton and zooplankton. The Phytoplankton Colour Index (PCI) provides a proxy colour indicator of phytoplankton biomass whereas other indicators can also show abundance changes in phytoplankton and zooplankton. PCI for the northern North Sea during the most recent decade is 67% higher than in the 1960s, and over the last five years is 29% higher than the mid to late 2000s (State of Nature Partnership, 2019). Similarly, in the English Channel the PCI is 95% higher in the last decade and 18% higher in the last five years. Within groups of phytoplankton, regional differences are apparent. Increases in diatoms and dinoflagellates in the English Channel contrast with periods of decrease and overall stability in the northern North Sea which have been attributed to differences in trophic pathways and differing roles in the carbon cycle (OSPAR, 2017).

As also detailed in previous CCRAAs, the impact of warming seas varies geographically and by species, and also due to differences in interactions between species. Long-term increases in phytoplankton biomass of 21% and 13% have been reported in the coastal and open North Sea, respectively, between the 1980s and early 2000s. More recently however, estimates of primary production in the North Sea indicate a declining trend as well as changes in species composition and timing of seasonal events, with knock-on effects on zooplankton abundance and fish recruitment, including for cod, herring, haddock, whiting, sprat, and sandeel, as analysed through a standard recruitment index (Capuzzo *et al.*, 2018). These changes in phytoplankton growth and productivity are associated with both the direct effects of warming together with reduced mixing of surface and bottom water layers, which limits supply of nutrients from bottom waters reaching phytoplankton at the surface. The same study also found a significant correlation between decreased primary productivity and a decrease in riverine dissolved nutrient concentrations, notably reduced P in riverine inputs whereas N concentrations remain more unchanged, meaning some locations (notably the southern North Sea) have become more severely P-limited for phytoplankton growth.

Regarding zooplankton, small copepods, which tend to dominate the southern and central North Sea, appear to have declined in correspondence with reduced phytoplankton primary productivity (Capuzzo *et al.*, 2018). The total abundance of large copepods seems more variable but with a composition that has changed to an increasing dominance of more temperate species as a result of climate change. Over the last 50 years, total *Calanus copepod* biomass in the northern North Sea has declined by 70% due to regional warming, with resultant consequences for other dependent species. Warming temperatures in the NE Atlantic have also brought smaller warm-water copepod species into UK waters. Plankton species with warmer-water affinities (e.g., *Calanus helgolandicus*) have now moved northwards from the Celtic Sea to replace cold-water species (e.g., *Calanus finmarchicus*) in most of the seas around the UK. Changes in community composition and seasonal productivity have then been inferred to have cascading impacts at higher trophic levels including to fish and seabirds (see below). The abundance of planktonic larvae has increased in most areas associated with increasing temperatures (State of Nature Partnership, 2019). Similarly, increases in the abundance of the warm water kelp species, *Laminaria ochroleuca*, have been observed at sites around Plymouth, the Isles of Scilly and Lundy Island. Conversely, although evidence remains limited, warming has been linked to negative impacts on cold water corals (Moore and Smale,

2020), as for example through constraints on the dispersal and settlement of the larvae of the cold-water coral *Desmophyllum pertusum*.

For shallow-water shelf habitats, there is similar evidence for expansion of warm-water species (Moore and Smale, 2020). For example, there is good evidence for changes in UK kelp species abundance linked to altered sea temperatures, notably expansion and increased abundance of the warm-water species, *Laminaria ochroleuca*, including into more wave-exposed conditions.

Some nearshore habitats, notably seagrass beds are vulnerable to increased turbidity and pollution due to sediment runoff from land. Analysis of mapped UK seagrass extent against past records and habitat suitability assessments indicates that at least 44% of habitat has been lost since 1936, 39% since the 1980's (Green *et al.*, 2021). Shallow marine habitats, including seagrass beds, kelp beds, and serpulid reefs, are also vulnerable to disruption from increased turbulence due to changing patterns of storm frequency and intensity. Although evidence for long-term trends to increased storminess is often location-dependent, and also complicated by shorter-term variations such as through the North Atlantic Oscillation, some recent periods (notably winter 2013/14) have been notable for a clustering of successive cyclones following a storm track over the UK. This clustering can mean there is insufficient recovery time for the habitat, placing it in an increasingly weakened state and also vulnerable to other pressures.

Impacts on some species also have wider importance because they have a key ecosystem function, such as those species that help build habitat for other species ('ecosystem engineers'). Kelp are notable examples of these habitat-forming species (see also Risk N5 for carbon storage implications). For *Laminaria hyperborea* (the dominant habitat-forming kelp species in Scotland), modelled predictions showed northward expansions coupled with significant loss of suitable habitats at southern range margins (Assis *et al.*, 2016). Recent research from the western English Channel has shown that in addition to direct effects on biodiversity through shifts from cold-water species to warm-water species, indirect effects occur through modification of assemblages (both stipes and holdfast assemblages) which has led to reduction in both diversity and overall biomass (Smale *et al.*, 2015; Teagle and Smale, 2018). Moreover, analysis in the same regional location has shown that warm-water kelps had a much greater turnover of biomass (both accumulation and decomposition increased by ca. 80%) compared to cold-water species despite similar morphological and taxonomic affinities (Pessarrodono *et al.*, 2019). This was due to accumulation and decomposition of organic matter becoming year-round rather than over a much shorter discrete period, including a large increase in detritus formation and decomposition rate (increasing by a factor of 6.5). Such modifications to net ecosystem primary productivity will affect both the host ecosystem (including to higher trophic levels) and adjacent ecosystems due to nutrient transfer in currents. Further effects may occur through changes in sea urchin dominance (and barrens) for UK kelp populations but in addition to sea temperature, other environmental factors, and predation pressure on pelagic larvae, will influence sea urchin recruitment success.

In this context, other ecosystem engineers can be highlighted that through their sensitivity to changing climate conditions may have wider implications for biodiversity, ecosystem stability and functioning. This includes cold-water corals, horse mussel beds, maerl beds, seagrass beds, and other biogenetic beds and reefs, that act to modify and stabilise the sea floor, each creating a

distinctive habitat. In addition to the direct effects of ocean warming, these ecosystem engineers can be vulnerable to skeletal weakening associated with ocean acidification (Küpper and Kamenos, 2018; Moore and Smale, 2000; Jeffreys *et al.*, 2020).

Whilst fisheries show the general large-scale pattern of northward movement of species, historic overfishing pressures have been the dominant influence, although in the last 10 years some commercial fish species have increased in abundance from very low baselines. Warming and associated oxygen solubility appears to be influencing maturation age, growth rates, and maximum fish size, as warming tends to cause faster maturation and smaller maximum body size (Baudron *et al.*, 2014; Genner *et al.*, 2017; Wright *et al.*, 2020). Warming temperatures also affect timing of spawning among species, as has been observed with earlier spawning for cod (McQueen and Marshall, 2017). In some cases, differential warming responses between predator and prey have been inferred to be leading to a phenological mismatch across trophic levels with wider ramifications for ecosystem functioning, as for example with delayed development of the lesser (Raitt's) sandeel by comparison with earlier emergence of its copepod prey (Régner *et al.*, 2017, 2019). Meta-analyses and reviews of fisheries from different ecoregions continue to suggest that populations that have experienced more severe overfishing (in both intensity and duration) were most likely to be negatively influenced by warming, especially when this is combined with more rapid warming rates in excess of 0.2°C per decade (Free *et al.*, 2019; Pinnegar *et al.*, 2020).

Amongst UK demersal species, there have been increases in the populations of smaller-bodied, non-commercial species (Montero-Serra *et al.*, 2015), whilst pelagic species show a shift in recent decades from cold-water assemblages (e.g., herring) to warmer-water assemblages (e.g., mackerel, sardine and anchovy), probably further facilitated by changes in prey species (Lynam *et al.*, 2017). As noted above there is evidence that climate-driven declines in primary production and copepod arrival in the North Sea have led to declines in fish stock recruitment for some commercial species, including cod, herring, whiting and sprat. The combination of predator-prey (top-down) and resource-based (bottom-up) trophic controls has been suggested to explain the apparent slow recovery from overfishing of key species such as cod (Lynam *et al.*, 2017).

Another taxon that is potentially vulnerable to changing trophic interactions are elasmobranchs because of their reliance on zooplankton. For example, basking sharks gather in specific locations to feed on zooplankton at specific times of year, such as in the Sea of Hebrides between June and October (which is one of the main reasons for its designation as a prospective Marine Protected Area). However, further data on this taxon are required to more fully assess the climate change risk.

Shellfish are also sensitive to the effects of ocean warming and other pressures, both in the larval, juvenile and adult stages of their life cycle. Based upon this known sensitivity, we identify that the consequences may extend to potential catch implications for key species such as scallop, crab, lobster, and nephrops that can be of particular importance to some local coastal communities. However, although these sensitivities are known from species distributions relative to climate and other environmental conditions, there is as yet no clear data on long-term trends.

Since CCRA2, evidence is now increasing that declines in the abundance and nutritional quality of sandeels has reduced the breeding success and populations of some seabirds (notably surface-

feeding species such as kittiwake) although mechanisms remain to be fully established (Carroll *et al.*, 2015, 2017; MacDonald *et al.*, 2015; Regnier *et al.*, 2019; Mitchell *et al.*, 2020; Moffat *et al.*, 2020)). Sandeel populations seem to be affected by increasing sea surface temperature, the timing and strength of ocean stratification, and in mismatch in reproductive timings with availability of copepod prey (which are moving northwards), in addition to fishing pressures and pollution. Distinguishing causes and effects between these multiple stresses can therefore be difficult. Consequent effects on individual seabird species seem to be related to the location and timing of loss of prey species, and to a varying extent may be buffered in those seabird species that can access prey throughout the deeper water column rather than just surface waters. Improved use of tracking data and species distribution modelling is now being developed to provide more refined analysis of 'hotspot' locations that have a strong relationship with the breeding success of seabirds (Cleasby *et al.*, 2020).

There have also been other important changes in UK seabird populations (including breeding success) and distributions, including an ongoing decline in the UK seabird index defined based upon 13 key species (Defra, 2020b). These impacts are described in further detail in Risk N17.

Regarding marine mammals, the ranges of cold-water species, such as white-beaked dolphin, are contracting, whilst warm-water species are expanding (see Risk N15), but the role of climate change remains poorly understood. Adequate data is only available to determine trends for three cetacean species in the North Sea (harbour porpoise, white-beaked dolphin and minke whale), suggesting populations have remained stable (State of Nature Partnership, 2019). Better data is available for seal numbers, although the role of climate change also remains poorly understood. These data indicate that between 1994 and 2014 grey seal numbers increased, whilst harbour seals numbers decreased on the north and east coasts of Scotland but increased on the east coast of England and on west coast of Scotland. These changes in distributions are now being further investigated to confirm these patterns.

Finally, our assessment of known species sensitivities is that changes in ocean temperatures, circulation and salinity are very likely to be causative factors in the decline of some salmonids in UK rivers, notably the Atlantic salmon (cf. Olmos *et al.*, 2019), which has added importance because of its high economic and cultural value (see Risk N11) and also possibly some species of eel. Again, the exact causes are difficult to distinguish with high certainty due to the interaction of multiple factors acting on species with a complex life cycle, which also spend key stages of their lifetime in freshwater habitats (Risk N11).

#### 3.15.1.2 Future risk (N14)

UKCP18 and other future climate projections simulate continued ocean warming to 2100 in the range of 0.2°C to 0.4°C per decade, although with varying geographic patterns and punctuated by more extreme warming periods. This warming trend implies that it is almost inevitable that there will be major changes in UK marine biodiversity and fisheries, especially if the future pathway is towards the upper end of the climate projections. As highlighted above, warming also interacts with other marine phenomena stimulated by a changing climate, notably acidification, salinity, oxygen depletion, and changes in stratification and circulation patterns. In addition, non-climate socio-

economic drivers will continue to have an influence, including through changes in demand for fisheries and changes in pollutant loads, and cumulative pressures can be further exacerbated by coastal developments, aquaculture, offshore wind farms and other marine renewables. These multiple interactions and the current limited data on changes occurring in the present epoch (as described above) mean that details on the expected future changes remain rather uncertain despite their apparent inevitability (Cheung *et al.*, 2016). Furthermore, most studies of marine biological responses consider long-term changes in average temperature, and more rarely investigate the consequences of extreme events, including potential threshold effects, therefore this also remains an important source of uncertainty.

As described in detail for CCRA2, warmer waters have less oxygen solubility and carry less dissolved oxygen to lower parts of the water column, increasing the strength and duration of stratification, and further exacerbating the risk of low oxygen zones, including hypoxic conditions in coastal waters. Low oxygen conditions provide especially challenging conditions in the context of fish physiology and therefore will impact on the future of fisheries, although again important uncertainties remain (Townhill *et al.*, 2017). Oxygen concentrations in UK seas are projected to decline more than the global average, especially in the North Sea, with models indicating by 2100 the decline could be up to 11.5% (compared to a global average of 4%) (Mahaffey *et al.*, 2020). Projections for UK shelf seas also suggest that thermal stratification will occur for longer, typically starting a week earlier and ending 5–10 days later (Sharples *et al.*, 2020). In addition to oxygenation issues, reduced mixing of nutrients may have negative impacts on primary productivity whilst also increasing the duration, severity and distribution of HAB species and HAB events.

Regarding acidification, the Regional Ocean Acidification Modelling (ROAM) study, which used a high-end scenario of atmospheric CO<sub>2</sub> concentrations reaching 940 ppm in 2100<sup>34</sup> () has projected that average pH for the continental shelf could drop by up to 0.366 by 2100, with coastal areas having a greater reduction (Humphreys *et al.*, 2020). This change in pH (hydrogen ions) would imply an increase in acidification of over 100% compared to the present. The same high CO<sub>2</sub> concentrations pathway would imply bottom waters would become corrosive to more-soluble forms of calcium carbonate (i.e., aragonite) by 2100 although this pathway represents an upper extreme scenario. The same projections suggest up to 20% of NW Europe shelf seas may experience undersaturation for at least one month of each year with episodic undersaturation events beginning by 2030.

A consistent feature of future climate projections (including those associated with UKCP18) is the weakening of the Atlantic Meridional Overturning Circulation (AMOC) due to freshening in the Arctic and other related factors. The importance of this for the marine environment lies in its large-scale oceanographic influence on the transport of warmer sub-tropical water towards the UK and polar regions through the North Atlantic Drift (and Gulf Stream to the south). This is projected to affect the regional pattern of warmth and salinity in UK waters, strongly linked to the magnitude of global

---

<sup>34</sup> RCP8.5 concentrations pathway, which would either require CO<sub>2</sub> emissions above those consistent with current policies (see Introduction chapter: Betts and Brown, 2021) or a lower emissions scenario accompanied by strong climate-carbon cycle feedbacks (see Chapter 1: Slingo, 2021)

warming, but with regional anomalies due to the dynamic circulation response (McCarthy *et al.*, 2020).

For salinity, most projections suggest that UK shelf seas will become less saline as ocean circulation is further modified, with the greatest salinity decreases indicated for the North Sea (Dye *et al.*, 2020). For example, one notable recent modelling study suggests that climate-driven change in the North Atlantic and Arctic oceans could reduce transfer of oceanic water to European shelf seas (Holt *et al.*, 2018). By 2100, this could make the North Sea function more like an enclosed estuary in status than an open-shelf sea with decreased salinity and oxygen levels and significantly increased temperature and stratification, resulting in potential major consequences for the existence of many species, especially if pollution and eutrophication problems continue and become exacerbated. More generally, future projections for increased stratification in the NE Atlantic due to oceanic thermohaline changes would have implications for a wide range of taxa, although evidence on this is limited (some tentative associations are discussed in 'Current risk' including seabirds and sand eels).

These changes have major implications for species and habitats of high conservation value. For cold-water corals and maerl beds, ocean acidification has potential to cause significant corrosion damage, particularly of the non-living structures that provide structural support for the living surface layer, although confidence again remains limited in future projections (Jeffreys *et al.*, 2020). Following the upper-end emissions pathway of RCP8.5 would imply substantial decreases in seafloor habitat suitability for cold-water corals in the North Atlantic, suggesting that ca. 85% of existing features would become exposed to increasingly acidic waters by 2060. This upper end pathway would also imply by 2080, that summer warming could exceed the thermal tolerance of the main reef-forming cold-water coral, *Desmophyllum pertusum*, at the Mingulay reef complex off NW Scotland (State of Nature Partnership, 2019).

Regarding future projections of impacts from acidification, an important uncertainty to recognise is the adaptive capacity of species to respond to this stress. Although several studies have investigated phenotypically plastic responses of species through shorter-term (usually single-generation) experiments, there has been rather less research on transgenerational responses and genetic adaptation, and this limited research suggests that longer-term adaptation responses may partly mitigate adverse effects (IPCC, 2019). Current evidence suggests that crustaceans will be more ecologically resilient against acidification as compared to lesser resilience with molluscs, but responses in fin-fish remain rather more uncertain.

The general pattern for future change is the further replacement of cold-water species with warm-water species, with the rate of change dependent on climate change scenario and regional sensitivities. For example, models project that cold-water kelp species could be lost from southern England and Wales by the end of the century (Moore and Smale, 2020). Future warming is also very likely to continue to shift the geographical distribution of primary and secondary plankton production northwards, also influencing oxygen production and ocean carbon storage (Genner *et al.*, 2017). Warming may further decrease mean plankton community body size, with consequences for fishes, and marine mammal and seabird populations, although these changing inter-relationships remain a major uncertainty. Individual species responses will depend on their physiology and thermal tolerance, which can then potentially vary further due to acclimation (over the lifespan of

the individual) and adaptation (over evolutionary time), influencing both species diversity and abundance, and interactions across trophic levels. It is also likely that thermal stress will increase the prevalence of disease in some species (see Risk N16).

For fisheries, rapid range shifts greater than 4 km per year are projected over the next century, with the shifts indicated to be more rapid for open water pelagic species than demersal species due to higher potential motility (Genner *et al.*, 2017). As discussed in detail in CCRA2, although expectations are generally that species composition will be substantially modified, implications for UK fish stocks and fish production remain uncertain and there is no clear consensus on the details of change beyond expected long-term declines in cold water species, such as Atlantic cod, to be replaced by warm water species (for opportunities see Risk N15) (Pinnegar *et al.*, 2020). However, a study of eight demersal North Sea species using a statistical model found these species were unlikely to move north to cooler waters, due to their dependence on non-thermal resources (including water quality, suitable depth and substrate) implying that 'new' demersal fisheries are unlikely to arise (Rutterford *et al.*, 2015). Instead, the thermal preference of species will determine local expansion or contraction of existing commercial species.

Recent evidence from modelling of coralline algae in Scottish waters has shown large-scale spatial declines in distribution under all IPCC RCPs (ranging from 38% decline under RCP 2.6 up to 84% decline under RCP 8.5), with the most rapid rate of decline up to 2050 (Simon-Nutbrown *et al.*, 2020). This modelling approach also indicates suitable areas for species presence that currently lack records of occurrence and also that refugia populations may persist in some locations despite climate change, both important issues for informing priority areas for future conservation efforts.

Similarly, process-based modelling on warming and acidification parameterised with experimental data has estimated substantial declines in UK catches of demersal, shellfish and pelagic fishes by 2050, especially due to decreased primary productivity, with losses compared to present projected to be ~£87 million per annum (Fernandes *et al.*, 2017). Detailed process-based modelling of key pelagic species in the NE Atlantic based upon their exploitation to maximum sustainable yield (MSY) has found that potential mackerel and sprat catches were projected to increase in both a RCP2.6 and RCP8.5 climate change scenario (Fernandes *et al.*, 2020). However, the same study found that, although herring and blue whiting catches were projected to increase under RCP2.6, decreases were projected for RCP8.5. Overall, this study found that potential catches increased in the northern area of the NE Atlantic but decreased in the southern area, due primarily to changes in temperature and primary production, and hence that shifting pelagic resources may destabilize existing international agreements and quota sharing. Furthermore, other modelling work also suggests climate change will modify fish community size-structure to the extent that current policy targets may become unviable (Queirós *et al.*, 2018).

Modelling is also further investigating the implications of future change for seabird populations, indicating that it is very likely that there will be major changes in species abundance and their distributions. For example, modelling has suggested that the North Sea could become an important wintering area for some species including common guillemot, razorbill, great black-backed gull and herring gull (Searle *et al.*, 2020). However, many species have strong ties to their traditional breeding colonies, which may constrain their capacity to move.

UK aquaculture is dependent on two core species, the Atlantic salmon and blue mussel. As both species are close to the southern limit of their European range, then future warming has implications in terms of loss of productivity through thermal stress, lower growth, reduced food conversion efficiency, and a higher incidence of parasites and pathogens (Risk N16). Warming may also reduce immunocompetence of farmed species (Callaway *et al.*, 2012). However, evidence describing impacts on future production in commercial systems remains limited. Research shows Atlantic salmon actively prefer to occupy a 16–18°C temperature zone within aquaculture cages, and they display an active avoidance of water warmer than 18°C, consistent with evidence suggesting that an optimal growth temperature range is 14–18°C (Oppedal *et al.*, 2011). Reductions in performance by 20–25% have been inferred when temperatures reach 16–20°C. Central future climate projections suggest temperatures will remain suitable for salmon farming in most existing areas until the end of the century and may increase growth rates, however warming would be increasingly likely to affect summer and autumn aquaculture in Northern Ireland and the south of Scotland. By contrast, a high-end scenario could result in summer sea temperatures consistently exceeding 18°C in most existing production areas by 2050. Rising sea temperatures is also likely to cause reduced dissolved oxygen availability in water, further impairing performance, and increasing hypoxia risk (Genner *et al.*, 2017).

Impacts have also been modelled for blue mussel production in Strangford Lough (Northern Ireland), with an average water temperature rise of 1°C predicted to lead to a 50% production loss, whilst an average rise of 4°C would lead to a 70% production loss (Ferreira *et al.* 2008). Acidification may reduce shellfish spat settlement but is currently considered to be unlikely to affect fin-fish farming (Callaway *et al.*, 2012).

The economic impacts of acidification on shellfish fisheries and aquaculture to 2100 has been estimated using different methodologies (Net Present Value - NPV; Partial Equilibrium - PE) and emission scenarios (medium emissions A1B; high emissions RCP8.5 scenario) (Mangi *et al.*, 2018). Using the NPV approach, the direct potential losses due to reduced shellfish production range from 14–28% of fishery NPV, which would equate to a potential annual economic loss of £3–£6 billion of UK GDP. Results using the PE model, which has probably more realistic assumptions, assessed the total loss from shellfish production and consumption at £23–88 million.

Further research is required to investigate changing parasite loads in aquaculture. For example, *Mytilicola intestinalis* which is a copepod parasite of the mussel *Mytilus edulis*, is known to depress feeding performance at water temperatures of 22–23°C in UK waters, which may become an increasing risk factor, especially for southerly locations, in a high climate change scenario. Warming seas may also allow establishment and spread of new pathogenic parasites and increased incidence of bacterial diseases, notably from *Vibrio* species (Callaway *et al.*, 2012) – these changing risks have important implications for human health (see Chapter 5, Risk H6: Kovats and Brisley, 2021).

### 3.15.1.3 Lock in (N14)

Fisheries management and its influence on the wider marine ecosystem may be susceptible to lock-in risks when catches are maintained beyond a sustainable level. Evidence has shown that fisheries are vulnerable to abrupt collapse in stocks when over-exploitation occurs, including excessive harvesting of juvenile fish, and this may be exacerbated by the additional pressures of climate change on fish recruitment. There are important socio-cultural factors involved within the fisheries sector, and these can mean that fishers continue to focus on particular species and fishing grounds despite declining stocks and the requirements for diversification.

It has also been suggested that designation of Marine Protected Areas (MPAs) may be susceptible to lock-in risks, particularly where these are set up on the basis of habitats associated with historic marine climate suitability that may become less suited in future (Watkiss *et al.*, 2019). Hence, MPA designation needs to also include the dynamic effects of climate change in setting conservation objectives. In some cases (although not all), physiographic features that influence high biodiversity value may give a clearer indication of future nature conservation potential rather than the past or present distribution of species and habitats: this approach is being developed for some MPAs in Scotland using larger-scale features such as ocean fronts, sea-mounts, shelf banks, shelf deeps, and continental slopes (e.g. Sea of the Hebrides, Southern Trench, Shiant East Bank) (NatureScot, 2021).

### 3.15.1.4 Thresholds (N14)

Thresholds are known to be important in the marine environment but usually poorly understood. In addition to temperature-based thresholds, such as through physiology and thermal tolerance limits, climate-related thresholds are postulated for salinity, oxygen demand and acidification. However, in each case the threshold will relate to an individual species and may be difficult to identify due to the interaction of multiple factors on that species.

The CCC Thresholds project (Jones *et al.*, 2020) assessed the impact of higher temperatures on cod stocks in UK waters using a threshold annual average sea bottom temperature of 12 °C. This analysis used data from a NW European Shelf simulation covering the time-period 2000 – 2099 in conjunction with the HadGEM2-ES climate model and high-end climate change forcing (RCP8.5) consistent with a 4°C world. As the temperature threshold shifts northwards with global warming, the assumed climate space for cod is defined to become restricted to Scottish waters in the Atlantic and to the northern North Sea (northern parts of English waters only and Scottish waters). The same study also assessed thresholds in terms of changing Pacific oyster distribution which can be interpreted as an opportunity (Risk N15) or as an invasive threat to existing species (Risk N16).

In addition to thresholds occurring when incremental change reaches a critical level, we can infer based upon known sensitivities that it is highly likely that the increased frequency of some types of extreme events (e.g., marine heatwaves; deoxygenation; freshening and salinity pulses) will be responsible for triggering irreversible changes including species extirpation or even potentially larger-scale extinctions. In addition, actual temperature thresholds may be lower than assumed when just using a simple relationship with maximum temperature, because physiological thresholds

can exist across different stages of a species life cycle, especially for fish, hence these ‘thermal bottlenecks’ can further exacerbate a species inherent vulnerability (Dahlke *et al.*, 2020).

There is also evidence as indicated by a general review of the evidence (IPCC, 2019) that critical thresholds for some marine ecosystems will be reached at relatively low levels of global warming, therefore almost certainly in a 4°C warming world, but possibly averted in a 2°C world. Globally much attention has been focussed on warm-water corals but other sensitive ecosystems that are relevant from a UK perspective include kelp forests and seagrass communities (Smale, 2020), especially as related to a shift from cold-water species to dominantly warm-water species and resultant influence on ecosystem functioning (Teagle and Smale, 2018; Pessarodona *et al.*, 2019). Furthermore, it is very likely that there are ecological thresholds associated with changes in other climate-related phenomena, such as acidification and deoxygenation, and moreover that these critical thresholds may also have an ocean-depth related component (IPCC, 2019).

### 3.15.1.5 Cross-cutting risks and inter-dependencies (N14)

Marine ecosystems are fundamentally interconnected therefore the general scientific consensus, both globally and for the UK (IPCC, 2019; MCCIP, 2020), is that climate change risks to marine biodiversity and ecosystem functioning can be anticipated to have a severe effect on fisheries production and hence on fishing communities and businesses. Similarly, negative impacts on fisheries can have consequences throughout the whole ecosystem as predator-prey relationships are modified. In addition to fisheries, marine ecosystems provide many other ecosystem services including for the carbon cycle and oxygenation, and for their cultural benefits. The likelihood of major reorganisations in marine ecosystems, including through large-scale changes from weakening of AMOC (McCarthy *et al.*, 2020), therefore, is very likely to lead to multiple cascading and feedback-type effects both on land and at sea.

Risks to fisheries have particularly important implications for those coastal communities that have a high stake in this sector, either through direct involvement in fishing or aquaculture, or related activities such as processing or distribution. Changes to fish stocks or the effects of changes in policy may therefore have severe localised impacts based upon these interdependencies, and this may also extend to exacerbation of inequalities in those communities (see Chapter 5: Kovats and Brisley, 2021). In addition, climate-related movements in fish stocks, such as shifts further north in commercially important cold-water species, have implications for fisheries businesses (see Chapter 6); for example, this may require further travel by fishing vessels, or longer-term decisions such as relocation of operational bases or processing facilities. Furthermore, there are cross-cultural implications for marine heritage (e.g., archaeology) and for the diverse cultural interactions that occur between coastal communities and the marine environment (e.g., traditional fisheries; locality foods based upon fin-fish, shellfish or other produce).

These cross-cutting interactions have been further investigated in terms of the wider impacts of Marine Protected Area designation, showing that these have an important influence not only for biodiversity objectives but also for wider socio-economic issues, including for fisheries, aquaculture, seafood processing, tourism, and community engagement with marine issues (Scottish Government, 2020b).

#### 3.15.1.6 Implications of Net Zero (N14)

The marine environment has a key role in the carbon cycle with marine habitats such as seagrass beds and many marine species actively sequestering carbon, although the rate of sequestration is likely to be affected by warming of the seas and by acidification impacts on both individual species and community interactions. Some species, communities, and habitats will be more resilient and adaptable to these changing conditions, and this will also be influenced by the presence or absence of other (non-climate) pressures. Marine environments are not currently included in national GHG inventories and therefore the considerable potential they provide to reduce GHG emissions, including through further habitat restoration, is not included currently in the CCC (2020) Net Zero scenarios (ostensibly, this is due to the challenges in obtaining robust data for emissions/sequestration rates but as noted elsewhere for the LULUCF sector, uncertainty in spatial/temporal variations is inherent to the natural environment). Conversely, further degradation of marine ecosystems acts to reduce their carbon storage capacity and contributes to atmospheric CO<sub>2</sub>, therefore a more complete assessment of progress towards Net Zero would include this in terms of balancing GHG accounts through national inventories.

In addition, the Net Zero scenario features a large expansion in offshore renewables, which may have implications for marine biodiversity, notably seabirds, through collision and displacement unless carefully planned (e.g., Peschko *et al.*, 2020). Research is still in the early stages of assessing these impacts, but in some cases they may also have positive impacts: for example, analysis by Slavik *et al.* (2019) of blue mussel (*Mytilus edulis*) and other epifauna accumulations on turbine structures found that they could lead to significant changes in regional annual primary productivity (up to 8%) in the wind farm area, and similar magnitude changes in daily productivity also at locations farther away from the wind farm.

#### 3.15.1.7 Inequalities (N14)

As identified above, changes in fish distribution and impacts on fisheries may have resultant impacts for communities (usually in coastal areas) that have a high degree of dependence on these resources, as has occurred through such changes in the past. This may have important implications for progress on addressing societal inequalities in these vulnerable locations, although at present we have limited evidence as to how these inter-relationships between socio-economic and climate change factors may be affected at present and in the future (see also Chapter 5: Kovats and Brisley, 2021).

#### 3.15.1.8 Magnitude scores (N14)

Magnitude categories in Table 3.46 are based on expert judgement and assessed in terms of existing or expected impacts on biodiversity (including viable metapopulation sizes), ecosystem functioning, and ecosystem services (including fisheries but excepting carbon storage – Risk N5). This approach is also followed because indicators based upon species numbers or habitat area are only crudely indicative of systemic risks. Risk magnitude is assessed as at least medium at present (this is a

conservative assessment based upon available evidence) and increasing to high in the future under all climate projections. Confidence is medium (present) and low (future) due to limits on evidence availability (including some conflicting results) compared to the complexity of the marine environment, including key uncertainties such as species and trophic interactions and their effects on ecosystem function.

**Table 3.46** Magnitude scores for risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium	High	High	High	High
	(Medium confidence)	(low confidence)	(Low confidence)	(low confidence)	(low confidence)
<b>Northern Ireland</b>	Medium	High	High	High	High
	(Medium confidence)	(low confidence)	(Low confidence)	(low confidence)	(low Confidence)
<b>Scotland</b>	Medium	High	High	High	High
	(Medium confidence)	(low confidence)	(Low confidence)	(low confidence)	(low confidence)
<b>Wales</b>	Medium	High	High	High	High
	(Medium confidence)	(low confidence)	(Low confidence)	(low confidence)	(low confidence)

### 3.15.2 Extent to which current adaptation will manage the risk (N14)

#### 3.15.2.1 Effects of current adaptation policy and commitments on current and future risks (N14)

##### 3.15.2.1.1 UK-wide

As described below, the importance of the marine environment is increasingly recognised in national adaptation policies and fisheries also feature prominently, although detailed actions (that also include specific outcomes and plans for progress reporting) to address climate change risks remain rather limited based upon evidence available for this assessment. More especially, the plans are also constrained in terms of being robust against the full range of potential climate change pathways, hence limitations are particularly apparent in the context of managing risks at higher rates of climate change including in a 4°C world. In many regards, the scale and interconnectivity of

the marine environment acts to limit the range of viable adaptation options, but this further emphasises the importance of facilitating natural adaptation processes through maintaining and enhancing biodiversity (at all levels from genetic to ecosystems) and ensuring habitats are in favourable condition (including restoration where necessary).

The UK was a signatory to the Aichi 2020 targets agreed under the UN Convention on Biological Diversity (CBD, 2020) but has recognised that it has not met target 6 on '*Sustainable management of marine living resources*'. Although some UK fish stocks are showing signs of recovery in response to sustainable fisheries measures, not all stocks are yet fished at sustainable levels, and secondary effects continue through other ecosystem interactions (combined top-down and bottom-up effects: Lynam *et al.*, 2017 as discussed in section 3.15.1.1). New targets are now being set for 2030 under the same UN Convention on Biological Diversity. The UK is also a party to the OSPAR Convention to protect and conserve the NE Atlantic and its resources.

The official UK Government indicator (Defra, 2020a) shows that the percentage of fish stocks fished at or below levels considered to be capable of producing Maximum Sustainable Yield has increased from 7% in 1990 to 49% in 2017, and 33% of quota managed fish stocks are still reported as being harvested unsustainably (the status of the remainder is defined as 'unknown').

The UK Government's last assessment of progress towards Good Environmental Status (GES) under the EU Marine Strategy Regulations confirmed GES will not be met by 2020 for fish, commercial fish and shellfish, benthic habitats, breeding seabirds, and for non-breeding waterbirds in the Celtic Seas. GES had been achieved for four pressures (including eutrophication and contaminants), was partially achieved for four components of biodiversity, but was not achieved for three pressures and three components of biodiversity (including both fish and commercial stocks). Obligations that contain reference to condition monitoring for marine environmental change, including as previously required for the EU Water Framework Directive and EU Marine Strategy Framework Directive, will require further assessment with regard to the implementation of new UK legislation in the near future.

Marine Protected Areas (MPAs) have been identified as a key mechanism for enhancing resilience to climate change through high biodiversity and by providing ecological connectivity and space for facilitating range shifts. There has been a recent large increase in the extent of MPAs, especially since 2010, although monitoring of conservation actions in these areas is usually still in the earlier stages (Solandt, 2018; Tinsley, 2020). Modelling suggests there may be substantial warming-related changes to habitat within MPAs by 2100, which may lead to their current locations being suboptimal for the target 'feature' species or habitats used for their designation (Gormley *et al.*, 2013). Management measures have been documented in 60% of MPAs but only fully implemented in 10% of sites up to 2019 (State of Nature Partnership, 2019). In Scotland for example, 27 MPAs have specific fisheries measures in place and for a further 33 MPAs measures have been identified or are in the process of being developed in consultation with the fishing industry and other stakeholders. Other area-based measures, at 5 locations including voluntary reserves, restricted fisheries areas and fisheries closures, and safety exclusions zones around offshore windfarms, are also considered to contribute to the Scottish network. Despite these examples of progress and recent policy announcements on new MPAs (see below), recent assessments have identified a shortfall in

delivering the conservation objectives associated with the MPA network as represented by continued biodiversity loss (State of Nature Partnership, 2019).

Challenges remain regarding a successful implementation of MPAs. These include the lengthy time between design, objective setting, and plan implementation which acts to hinder adaptive management (Álvarez-Fernández *et al.*, 2020). In addition, defining a baseline assessment can be hindered by lack of data and the metrics used to define ‘good’ environmental status can be disputed (Solandt, 2018). Furthermore, although MPA networks may cover a large proportion of the seabed, the area within them for which management measures act to prohibit damaging fishing activity is typically much smaller which is especially of relevance for benthic communities affected by bottom fishing (Langton *et al.*, 2020). Hence, although fishing pressure is not necessarily reduced, the protected areas have particular value in protecting relatively pristine habitats from new fishing pressures, commonly those that have a higher ruggedness compared to other areas.

The new UK Fisheries Act 2020 has now been ratified by the UK Parliament. New provisions in the Act are designed to ensure that climate change impacts on fisheries will be accounted for including a new objective to move towards ‘climate-smart fishing’, although details for implementation of this are not yet available. The Act will provide a legal basis for all fish stocks to be harvested at sustainable levels including a sustainability plan for each fish stock that includes ‘the need for fish and aquaculture activities to adapt to climate change’. The Act also recognises that fish stocks are mobile, and that many are ‘shared stocks’ requiring negotiation with bordering countries to agree effective management, although the principles for this as they relate to climate change adaptation are yet to be established.

Regarding adaptation progress for all UK countries, a major constraint in assessing progress is the limited monitoring and data collection, both for biodiversity and fisheries (Frost *et al.*, 2016). For fish stocks, about 12% are identified as being of unknown status, including nearly all elasmobranch (shark and ray) stocks, whilst understanding of catches remains poor in the context of climate change and sustainable yields due to low levels of effective monitoring at sea (State of Nature Partnership, 2019).

#### 3.15.2.1.2 England

In England, nationally important habitats and species are protected through Marine Conservation Zones (MCZs) which act as designated MPAs and have been developed through a phased approach, including 27 sites in 2013, a further 23 sites in 2016, and a more recent commitment (2018) to create 39 more sites. However, detailed plans for most of the sites that would include adaptation objectives have yet to be published. The recent Benyon report for England has recommended the rapid creation of Highly Protected Marine Areas (HPMAs) in which all “extractive activities”, including dredging, sewage dumping, drilling, offshore wind turbine construction and even catch-and-release recreational angling, will be prohibited (Benyon *et al.*, 2020). Marine planning in England is administered by the Marine Management Organisation (MMO) which brings together planning, licensing and enforcement based upon a series of 10 plan areas. Fisheries are intended to be managed according to the provisions of the new UK Fisheries Act 2020.

Defra have also funded a marine pioneer project that has investigated new approaches to sustainable marine management consistent with the goals of the 25-YEP, including increased use of natural capital and the ecosystems approach, based upon case study areas in North Devon and Suffolk (MMO, 2021). This project identified key barriers regarding a lack of integrated planning and a chronic shortage of data to inform MPA management, and has provided a series of recommendations to address these barriers.

#### 3.15.2.1.3 Northern Ireland

The Northern Ireland Marine Plan was published for public consultation in April 2018 and includes climate change as one of its core components. The MPA network has been significantly expanded in terms of designated area (now at 2566km<sup>2</sup>) in recent years and the next stage will involve identification of necessary management measures to bring the network into 'favourable condition' (currently only 115km<sup>2</sup> is assessed as favourable). Northern Ireland is also involved in the MarPAMM project to trial new approaches to MPA management. Regarding fisheries, there was a consultation in 2014 for a new Fisheries Bill however the Fisheries Act (Northern Ireland: 2016) covered the enforcement of EU rules rather than a full update. With regard to Water Framework Directive *E. Coli* standards, only 2 out of 9 shellfish water protected areas (SWPAs) achieved compliance in 2019.

#### 3.15.2.1.3 Scotland

SCCAP2 (Scottish Government, 2019) identifies key actions for this risk as linked to the National Marine Plan, including that the use of the marine environment is spatially planned where appropriate and based on an ecosystems approach and adaptive management. It is also noted that fisheries will be managed taking into account changes in species distribution and abundance, and also including implementation of the vision proposed by the 2015 Inshore Fisheries Strategy; a key indicator for the SCCAP2 will be mortality consistent with achieving maximum sustainable yield. A climate change subgroup of Scotland's Farmed Fish Health Framework is developing further adaptation actions for the aquaculture sector, including monitoring of acidification impacts. The Scottish Government is also currently in consultation with stakeholders to inform and develop Scotland's Future Fisheries Management Strategy using an ecosystems-based approach. The additional designation of 4 new Nature Conservation MPAs and 12 SPAs will extend protected area coverage of Scottish seas to 37% with the aim of further decreasing existing pressures and to enhance overall resilience. The 2018 Parliamentary Report on the Scottish MPA network noted fisheries management measures in place and further measures being developed, as well as showing current progress towards achieving MPA objectives. A more recent report from Marine Scotland (Moffat *et al.*, 2020) has synthesised monitoring of the wider socio-economic impacts from MPAs based upon 4 case study locations, highlighting both positive and negative effects of MPA designation (including for fisheries, food processing, tourism, public engagement etc.) and their interactions with other changes, including climate change. Conservation and Management Advice documents that develop site-specific Conservation Objectives for each MPA, including climate change effects, have been drafted but are not yet published for the full suite of MPAs. Innovative approaches to MPA management planning are also being trialled in some areas (e.g. Outer Hebrides; Argyll) through the MarPAMM project. Further measures are also being developed (led by Marine Scotland) to reduce pressures (including fisheries) on sensitive Priority Marine Features

(PMF) outwith the MPA network. A PMF Review currently in progress aims to review the current PMF list (including to identify species at greater risk from climate change or important contributors to climate change mitigation), and to consider potential additions, including marine birds.

The Scottish Marine Assessment 2020 (SMA2020) has recently reported on the state of the marine environment, further confirming the threat from loss of biodiversity and climate change, including declining area of priority habitats in some marine regions, but also highlighting the challenges of interpreting the scale of impacts based on too few ecosystem monitoring sites and of understanding cumulative impacts (Moffat *et al.*, 2020). Although this means confidence in interpreting impacts remains low, current condition monitoring indicates that priority seabed habitats (e.g. seagrass, flame shells; mussel beds) have declined in extent, especially in parts of western Scotland and the Moray Firth (based upon seabed surveys in MPAs between 2011-2019), meaning current objectives to ensure 'no net loss' of priority habitats are under threat. The reasons for this remain to be fully established but have been attributed to overfishing and fishing gear, pollution sources, or potentially climate effects and climate change. The MPA assessment in SMA2020 also does not include the recent expansion in designation of MPAs since the end of 2018, for example the West of Scotland MPA and others designated in 2020.

#### 3.15.2.1.4 Wales

The new National Marine Plan (Welsh Government, 2019d) introduces a 20-year guiding framework to support sustainable decision-making for the seas of Wales, recognising the importance of ecosystem resilience, the value of biodiversity and the need to tackle climate change, also taking forwards EU Habitats Directive commitments (Conservation of Habitats and Species Regulations 2017). However, detailed implementation plans are yet to be provided and there is no specific mention of addressing impacts of climate change on fisheries within the Fisheries Sector Objective or for marine species. The Wales Marine Fisheries Advisory Group is a government/stakeholder group to discuss key policy issues but minutes show climate change risk has not been a priority on the agenda. Similarly, no explicit mention of climate change adaptation is provided in the MPA strategic Framework. The 'Prosperity for All: A Climate Conscious Wales' programme report identifies 5-year marine sector actions to improve the condition of wider marine ecosystems via Marine Protected Area Management (MC3) and research on marine ecosystems, marine services and marine heritage (MC4). For fisheries, the 'EU-exit and Our Seas' document outlines how Welsh Government will support the fishing industry and sector in its approach to developing fisheries post EU-exit using sustainable development principles focused on ecosystem services and long-term fisheries planning, including new opportunities and diversification (as also linked with the NRW Welsh Marine Evidence Strategy 2019-25). A variety of co-funded marine projects are also expected to enhance the evidence base (but not available at present) including the Bluefish project to assess vulnerability of commercial fish and shellfish in the Irish and Celtic Seas.

The risks from climate change are recognised in the Marine Area Statement published by Natural Resources Wales, including a specific theme for 'Building resilience of marine ecosystems'. The area statement details a number of goals, including shared responsibility with key stakeholders, improved research and understanding, and 'targeting resources' when an assumed good understanding of the issues is present.

### 3.15.2.2 Effects of non-Government adaptation (N14)

Regarding fisheries, Seafish, the industry trade body, produce annual watching briefs with the aim of informing the sector on latest developments in science, monitoring and policy. A previous Seafish report produced under the Adaptation Reporting Power conducted an initial risk appraisal for the sector. Whilst recognising increased exposure for the sector, this horizon-scanning assessment generally concluded that climate change from an industry perspective was a longer term and less urgent priority at that time compared to other issues (Garrett *et al.*, 2015). Much of the emphasis to-date has been on voluntary initiatives, but these require active uptake by the fishing industry, and we have very limited information on how this is happening or contributing to adaptation progress, especially in the context of modern fisheries technology.

With regard to biodiversity conservation, restoration initiatives established through local marine partnerships increasingly have a climate change component and are integrated with matching long-term objectives, as for example with the Seagrass Ocean Rescue project which is trialling seagrass restoration at Dale Bay, west Wales. In England, a broad-scale assessment of potential restoration/recreation sites for seagrass and biogenic reefs has been developed to provide a basis for more detailed appraisal and implementation at local level (MMO, 2019). Similarly, the DEEP project in Scotland is aiming to restore oysters to the Dornoch Firth with the resulting biogenic reef also have benefits for water quality in addition to biodiversity.

Natural adaptation processes, aided by human activities (intentional or unintentional), can also produce unexpected surprises in the marine environment. For example, native oyster assemblages have recently been found in Belfast Lough (Northern Ireland) after being absent for more than 100 years. It is believed that the most probable explanation for this change is that adult oysters were introduced through commercial Blue Mussel fisheries and they have subsequently become established in small colonies, possibly further benefiting from recent bathymetric and hydrodynamic changes through the deepening of the central shipping channel (Smyth *et al.*, 2021). Another potentially important example is evidence that suggests kelp in coastal waters can help rehabilitate their immediate environment by lowering the acidity levels, which if supported by further investigation could provide a natural buffer against increasing acidification risks (Silbiger *et al.*, 2018).

### 3.15.2.3 Barriers preventing adaptation (N14)

In fisheries, market forces and the pressures to increase production can be in conflict with long-term sustainability objectives. These are often accompanied by political pressures, as related to national fishing quotas, which can act against the international collaboration needed to manage mobile fish stocks across territorial boundaries. These challenges are especially exemplified when fish move to new areas because the process of negotiating quotas and matching these to changing fish population distributions and sizes continues to be an uneasy compromise between science and political expediency (Scottish Parliament Information Service, 2018). There are also important socio-cultural factors underlying attitudes to change in the fishing industry and in local fishing communities (e.g. Reed *et al.*, 2013). These cultural norms and their influence on decisions such as

gear investments predispose fishers to target specific stocks or areas, hindering attempts to encourage diversification and other forms of adaptation.

For both biodiversity and fisheries, the complexity of marine ecosystems is a major challenge for effective adaptation, especially due to current constraints on monitoring data and therefore understanding of processes. Management decisions are typically based on simplified indicators which may not necessarily be representative of the wider ecosystem as for example with lack of knowledge on the vast majority of unmonitored and unregulated fish populations. This means that management plan objectives in MPAs and other strategic plans are often generic, subject to lengthy delays and rather static (Álvarez-Fernández *et al.*, 2020).

For some years, Wales and Ireland have benefitted from projects funded under priority 2 (Adaptation of the Irish Sea and Coastal Communities to Climate Change) of the EU Ireland-Wales Programme 2014-2020. While the impacts of EU-exit are not yet fully understood, the loss of this funding could have important implications for ongoing collaboration and monitoring of change in the Irish Sea.

#### 3.15.2.4 Adaptation shortfall (N14)

While there is an increasing recognition of the importance of the marine environment in national adaptation policies and of climate change in marine plans, there is still a lack of detailed actions to address climate change risks that include specific outcomes and associated plans for progress reporting. Notable examples of this shortfall are the limited development of targeted adaptation plans for both individual MPAs and the protected area network as a whole, and for fisheries both in terms of individual species and their interactions with other species. At present, there is limited detail on how climate change adaptation will be included in the fisheries management plans defined by the new Fisheries Act 2020. There are also limitations in existing condition monitoring which hinder robust adaptation planning. We assess there to be an adaptation shortfall for all UK waters (England, Scotland, Wales, and Northern Ireland), although confidence remains low due to limited available evidence on adaptation actions.

#### 3.15.2.5 Adaptation Scores (N14)

Table 3.47 Adaptation scores for risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures			
Are the risks going to be managed in the future?			
England	Northern Ireland	Scotland	Wales
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.15.3 Benefits of further adaptation action in the next five years (N14)

Although adaptation objectives are sound in principle, including recognition of the need for a shift towards ecosystem-based management, our assessment is that they are also rather general and require both more expeditious implementation of current actions and additional initiatives to manage more effectively changes in risk. These issues are especially relevant for actions that seek to enhance natural adaptation in ecosystems because the scope for human intervention is usually more restricted in the marine environment (including schemes such as species relocation that are employed in terrestrial/freshwater environments). A priority should therefore be actions that reduce other environmental stressors, including pollution and overfishing, as recognised by MPAs and recent proposals to designate Highly Protected Marine Areas (HPMAs – see Benyon *et al.* 2020), and to enhance both their individual and collective (network) functionality through improved incorporation of clear objectives for climate change adaptation. New approaches to test application of these principles in practice are now being trialled, including the Defra marine pioneer case studies (North Devon and Suffolk), which have provided innovative suggestions for enhancing the marine environment (MMO, 2021) and through which ecosystem-based adaptation could be further incorporated.

In fisheries, much could be further accomplished by better implementation of existing measures through improved management and institutional arrangements (policy; legal; fisheries planning; conservation objectives; risk preparedness) (Poulain *et al.*, 2018; Gaines *et al.*, 2018). Diversification into new species and avoidance of negative by-catch losses will require gear and catch-method innovations, including new information-sharing networks to better target new species and avoid other species, particularly in mixed stocks with changing composition. This is likely to require further realignment of incentives to support sustainable fishing, including through further development of Ecosystem-based Management (EBM) for which a range of practical approaches have now been investigated in different contexts (e.g. Borja *et al.*, 2016). Pressure on existing stocks may also be alleviated by schemes to encourage the UK public to diversify their choice of fish beyond a few familiar species (notably cod and haddock) and through further development of certification schemes to indicate sourcing from sustainable sources (e.g. Marine Stewardship Council standard: MSC, 2020).

Enhanced proactive adaptation also requires establishing a sounder conceptual and management basis for key indicators such as ‘maximum sustainable yields’ (MSY) in the context of both short-term climate variability and longer-term climate change, including anticipatory application to new species in UK or international waters. In addition, MSY needs to be better framed within the context of ecosystem-based management (EBM), rather than individual species-specific targets in isolation, recognising also habitat needed for both the stock fish and other interdependent species to function. Nevertheless, it also needs to be recognised that the complexities of EBM may necessitate long lead-times for implementation, and that effective management of stocks also will require continued and probably enhanced international cooperation.

Improvements in adaptation for both biodiversity and fisheries are also strongly linked to better monitoring of ecological changes and their relationship with the physical environment (Mieszkowska *et al.*, 2014). Long-term assessment of ecosystem restoration projects is essential but

complex because ecological processes such as succession act to alter the consequences of restoration through time, particularly in highly dynamic ecosystems (Boerema et al., 2016). Monitoring is very likely to benefit increasingly from enhanced use of remote sensing and its use in combination with other observations to establish improved time series and spatial data. A further benefit from monitoring is likely to be better use of forecasting systems to understand and predict variability over different timescales, from seasonal to multi-annual, and hence their use in both fisheries and biodiversity management (e.g. for setting fishing quotas).

#### 3.15.3.1 Indicative costs and benefits of additional adaptation (N14)

There is more information emerging internationally on adaptation options for fisheries (Poulain et al., 2018), although most of these are extensions of existing actions including institutional adaptation (policy, legal, fisheries management and planning [including conservation and protection]), diversification (within and between the sector), risk preparedness and reduction. There is also information on the costs and benefits of these options (FAO, 2019). One study, Jones et al. (2015), identifies the net economic benefits of UK fishing fleets adjusting to the shifting fish stocks. It finds that net present value would fall in the situation where the fishing areas allowed under the Exclusive Economic Zone (EEZ) were retained as currently drawn. The study calls for investment into adaptive capacity within the industry. Watkiss et al. (2019) made an initial assessment of potential costs and benefits of some adaptation options for UK fisheries. They identified the potential benefits of an adaptive management approach for the fisheries sector, with a scale up in monitoring, scientific information and awareness raising, subsequently including this information in regular updates of fisheries policy (e.g. to set maximum catch potential for current species, include new species in policy) alongside awareness raising in the fishing sector. The Watkiss et al. (2019) study indicated that an adaptive management strategy would have positive benefit to cost ratios, through the value of information and enhanced decisions taken. It also looked at the potential costs and benefits of increasing MPAs to improve the marine environment in the face of climate change (more marine areas – with full protection – to deliver the same level of ecosystem service function/benefit), drawing on the economic literature on MPAs (Heal and Rising, 2014; Kenter et al., 2013; eftec, 2014; European Commission, 2017). This indicated that there would be net economic benefits of additional MPAs. Finally, it considered the question of whether other options might be introduced to ensure maximum sustainable yields are maintained under climate change, or to consider stricter policies. This found such measures would involve complex issues because of trade-offs (i.e. between enhanced efficiency and effectiveness of the fishing industry, versus greater pressure on maximum sustainable yields).

#### 3.15.3.2 Overall urgency scores (N14)

The evidence above suggests that major changes will occur to the marine environment under both 2°C and 4°C warming trajectories. Each of the UK administrations recognises the high importance of the marine environment and for seas and oceans to be good and sustainable condition, consistent with international agreements. However, current policy is rather generic in its commitments and lacks actions in sufficient detail to address these risks, notably targeted plans and associated measures to enhance and protect marine habitats and to urgently reduce fishing pressures so that

there is more scope to maintain fisheries at a sustainable level despite the increased challenges from climate change. Risks to this topic therefore have been assessed as 'More action needed', as further intervention is required across the administrations to better prepare for these changes, and indeed to better manage current changes.

<b>Table 3.48</b> Urgency scores for risks to marine species, habitats and fisheries from changing climatic conditions, including ocean acidification and higher water temperatures				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Medium	Medium	Medium	Medium

Additional actions include:

- Further development and regulation of the MPA network as associated with present biodiversity requirements and, importantly, expected future shifts in species distributions and implications for ecosystem functioning.
- Further reduction of non-climate pressures (overfishing, pollution etc.) to maximise potential for species and habitats resilience.
- Further development of habitat restoration initiatives.
- A clearer assessment and implementation of sustainable fisheries yields in the context of present and future climate change, and the wider ecosystem.
- Improved monitoring schemes to better assess progress on biodiversity and fisheries goals.
- Further research on the climate sensitivity of trophic interactions from plankton to fisheries, seabirds and mammals.
- Further research on the sensitivity of UK aquaculture species to multiple climate change drivers.

#### 3.15.4 Looking ahead (N14)

Many important knowledge gaps remain in terms of understanding the combined effects of ocean changes across multiple drivers. Enhanced experimental and modelling research to understand future changes needs to be better contextualised and evaluated against new and existing monitoring data throughout UK and international waters. Further investigation of ecosystem-based approaches in a climate change context requires a stronger emphasis on interdisciplinary frameworks that go beyond existing academic and research funding structures (Alexander *et al.*, 2018). Opportunities also exist to further capture the potential from historic monitoring and sampling programmes with regard to improved time series analysis, as for example conducted on acidification and calcification based upon comparing the HMS Challenger plankton samples from the 1870s with the present day (Fox *et al.*, 2020).

Regarding future projections, the vast majority of these have been conducted using the high emissions pathway that is consistent with the RCP8.5 climate change scenario. Although this notionally provides an upper bound on future change for use in risk assessment, it also results in an unbalanced assessment, therefore a broader range of RCPs are required in marine modelling projections.

### 3.16. Opportunities to marine species, habitats and fisheries from changing climatic conditions (N15)

- The arrival of warm water species into UK waters provides new opportunities for biodiversity and fisheries.
- The level of opportunity for this topic from changing climate conditions may increase from medium at present to potentially high in future, although there is considerable uncertainty.
- Much of the adaptation opportunity for marine species and new fisheries remains unrealised. The assessment recommends further investigation to improve information, awareness, and adaptive capacity for this topic.
- Realisation of these opportunities will also require that associated risks to the marine environment (Risk N14), including habitat availability and condition, are effectively managed.

#### Introduction

This topic assesses climate-related opportunities in the marine environment, with emphasis on ‘new’ species for UK waters as distinct from ongoing shifts in existing UK species (also recognising that such a distinction is not completely clear as changes may include re-colonisation). Its significance is related to implications for changes in biodiversity as well as ecosystem services, with the latter also covering changes to fisheries that impact on livelihoods and businesses. As with Risk N14, we are already observing major changes in the marine environment at present and expect to see greater changes in the marine environment in future. This indicates the level of opportunity may increase from medium (present) to possibly high in future, although there is considerable uncertainty, and the notion of losses and gains cannot purely be considered in objective terms. Evidence is best available currently from changes in the composition of fish stocks, but there is also some information on changing species movements. Much of this opportunity presently seems unrealised therefore ‘further investigation’ is recommended to improve information, awareness, and adaptive capacity for this topic.

It is very likely that EU-exit will have major implications, as with risk N14, most notably in terms of changes in fisheries policy (quota arrangements, regulations etc.) and the impact of any changes to international trade and markets, although final details on post-EU-exit arrangements are yet to become available. Similarly, any implications arising from the Covid-19 pandemic remain only speculative at present, although it is quite likely that some monitoring activities will have been adversely affected.

### 3.16.1 Current and future level of opportunity (N15)

#### 3.16.1.1 Current opportunity (N15)

Mean annual sea temperatures have shown a consistent warming trend since the 1970s, with coastal sea surface temperatures being 0.6°C warmer in the most recent decade compared to the 1961–1990 average (see Risk N14 for a fuller discussion of recent trends). In response to this warming, studies across a range of taxa show poleward shifts in species distributions, advancements of the breeding seasons, changes in migratory patterns, and increased abundance of warm water species while cold water species decline (Genner et al., 2017; Hastings et al., 2020). The lack of barriers to movement means that some warm-water species such as red mullet, sardines, anchovies, seahorses and squid, have been assessed as moving north at rates of up to 50 km per year, which is rather greater than equivalent land rates that are more normally considered as the yardstick for climate change dispersion (Lenoir et al., 2020).

All six of the major UK pelagic species are dependent on temperature, with those species preferring warmer waters becoming more common across the region; similarly, abundance of demersal species has been associated with warming and thermal preference (Montero-Serra, 2015). Over the last 20 years, there have been expanding fisheries for warmer water species such as seabass and red mullet and new opportunities are developing for species such as Atlantic bonito, jack, and bluefin tuna. For example, after being mainly absent for over 50 years, Northern hake as a warm-water species has recolonised the northern North Sea. Similarly, the reappearance and increased abundance of bluefin follows a similar pattern that has been explained by changing patterns of ocean and climatic variability, and in particular by the Atlantic Multidecadal Oscillation (AMO) (Faillietaz et al., 2019). Increases in abundance are also evident for many of the smaller-bodied pelagic fish species (e.g. sardine).

Abundance of some shellfish populations in UK waters have also been linked with temperature, including larval and juvenile scallop (Shephard et al. 2010). Over recent years the Mediterranean mussel *M. galloprovincialis* has been found in northern European waters, often with *M. edulis* x *M. galloprovincialis* hybrids, and although this is probably due to human agency (e.g. shipping), these new and hybrid species are likely to be increasingly favoured by warming temperatures (Mathiesen et al., 2017).

For marine mammals, opportunities are increasing for warm-water species, which observations indicate are moving northwards. These include opportunities for striped dolphin, short-beaked common dolphin, and Cuvier's beaked whale (Evans and Waggitt, 2020). As with most observed data in biodiversity, sightings of new species in new locations are a key feature of marine records, however a fuller understanding of what this means in terms of long-term shifts in species range requires further and more detailed analysis in terms of whether it is a permanent shift or due to other factors, such as changing distribution of prey species.

### 3.16.1.2 Future opportunity (N15)

Future climate projections including UKCP18 indicate continued ocean warming to 2100 and beyond, with most projections in the range 0.2°C to 0.4°C per decade. Hence, it is our inference that it is almost inevitable that there will be major changes in marine biodiversity and fisheries, providing significant opportunities for warm-water species as cold-water species are displaced, but detailed evidence for individual species in terms of expected rates of change in occurrence and abundance remains limited. Complicating factors include differential species response rates, species interactions (especially across trophic levels), and changes in socioeconomic factors such as fishing quotas and pollution loads.

The response to warming will be strongly influenced by an individual species' physiology and its thermal tolerance range, which may be further modified by phenotype acclimation (over the lifespan of the individual) and evolutionary adaptation (over multiple generations). Warming is therefore likely to enhance abundance of favoured species through physiological and life cycle effects, or indirectly by having comparatively negative effects on competitors or predators, or indirect positive effects by increasing prey species. Furthermore, in addition to warming, other climate change related influences (e.g. changes in salinity; acidification) will also impact on opportunities for different species (see Risk N14).

### 3.16.1.3 Lock in (N15)

Potentially through lack of awareness of changing opportunities and the need for biodiversity and fisheries management objectives to adjust to these rather than continuing to pursue goals based upon historic species distributions.

### 3.16.1.4 Thresholds (N15)

As noted above, species physiology and thermal tolerance is a key factor influencing opportunities and these typically have discrete temperature thresholds. For example, the CCC Thresholds project (Jones et al., 2020) explored warming-related expansion of the non-native Pacific oyster from its current range, showing considerable expansion opportunities relative to future rates of warming, although in this case 'opportunity' may be at the expense of native species through ecosystem invasion (see Risk N16).

There are also very likely to be thresholds related to the rate of change which act to restrict opportunities. A more rapid rate of change in marine temperatures and other related factors (e.g. dissolved carbon dioxide and oxygen; salinity; extreme events) may occur faster than the adaptive capacity of individual species or communities to respond to that change (e.g. for marine vegetation).

### 3.16.1.5 Cross-cutting risks and inter-dependencies (N15)

There are very important inter-relationships between healthy marine biodiversity and ecosystems, and sustainable fisheries management (see Risk N14) which require careful assessment of opportunities in order that they do not have negative consequences for other species or locations. The changing nature of pests, pathogens and invasive species (Risk N16) will also impact on both risk

and opportunity. Opportunities in fisheries will be strongly influenced by societal demand either in the UK or in other countries through global trade.

### 3.16.1.6 Implications of Net Zero (N15)

There are potential implications through the impact on fisheries and aquaculture, although presently the marine sector remains a less-developed component of the Net Zero pathway. In some cases, opportunities may increase the carbon sequestration rate for some habitats allowing a greater net contribution to Net Zero targets.

### 3.16.1.7 Inequalities (N15)

No specific implications for societal inequalities associated with climate change were identified from existing evidence in relation to opportunities for marine species, habitats or fisheries.

### 3.16.1.8 Magnitude scores (N15)

<b>Table 3.49</b> Magnitude scores for opportunities to marine species, habitats and fisheries from changing climatic conditions					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	Medium  (low confidence*)	Med-High  (low confidence)	High  (Low confidence)	High  (Low confidence)	High  (low confidence)
<b>Northern Ireland</b>	Medium  (low confidence*)	Med-High  (low confidence)	High  (Low confidence)	High  (Low confidence)	High  (low confidence)
<b>Scotland</b>	Medium  (low confidence*)	Med-High  (low confidence)	High  (Low confidence)	High  (Low confidence)	High  (low confidence)
<b>Wales</b>	Medium  (low confidence*)	Med-High  (low confidence)	High  (Low confidence)	High  (Low confidence)	High  (low confidence)

Notes: Magnitude categories based on expert judgement and assessed in terms of existing or expected impacts on biodiversity (including viable metapopulation sizes), ecosystem functioning,

and ecosystem services (including fisheries but excepting carbon storage – Risk N5). This approach is also followed because indicators based upon species numbers or habitat area are only crudely indicative of systemic relationships. We assess the magnitude as increasing from medium at present to high in the future, although with a possibly lesser increase for 2050 under the lowest climate change projections hence medium-high. Confidence is low for all these assessments due to limited evidence across the full range of species groups, although this is better for fisheries due to the wider range of observations provided by researchers and industry.

*\* Confidence would be 'medium' for fisheries only.*

### 3.16.2 The extent to which current adaptation will manage the opportunity (N15)

#### 3.16.2.1 Effects of current adaptation policy and commitments on current and future risks (N15)

The policy context for this opportunity is generally the same as Risk N14 and is discussed in more detail in that section (including variations throughout the UK). In general, there is only limited mention of initiatives specifically related to new opportunities for marine habitats and species, or for fisheries. This means that the constrained responses from non-governmental sources, either in the biodiversity or fisheries sector, is not being recognised and covered by government policies and plans. In practice, however, there are important differences between the marine biodiversity sector and fisheries sector, with government generally expected to take the lead on biodiversity issues (although with significant engagement by NGOs) whereas the latter sector is industry-led both for capture fisheries and aquaculture.

A new UK Fisheries Act 2020 to define the policy position on leaving the EU Common Fisheries Policy has now been ratified by the UK Parliament. This will determine future management of fish stocks based upon a sustainable management plans for each species, including realisation of any potential opportunities from new species. The devolved administrations are also developing post EU-exit policy arrangements. The situation is complicated because fish stocks of commercial interest are mobile and fluctuate in time across international boundaries. In the greater North Sea and Celtic Seas, nine nations operate fisheries. At present, there is no quota for new species coming into these waters such as bluefin tuna for UK vessels, whilst opportunities from some other larger-scale species movements, such as Northern hake, will require further negotiation of changing quota arrangements.

For biodiversity, the continued future conservation of Marine Protected Areas (MPAs) will be important in providing habitats where new species of high biodiversity value can become established and hence opportunities could be realised, as there is good evidence that providing habitats in good condition aids in the movement of species and their colonisation of new areas (e.g. Airolidi et al., 2008). This is especially relevant for biogenic habitats that provide large amounts of nutrients and organic matter, together with a complex and varied habitat structure, that mean they act as hotspots for biodiversity and recruitment. Nevertheless, MPAs may need to be revised, including designation of new zones, to maximise the changing opportunities for biodiversity, including expected changes in species composition and an increased likelihood of the emergence of

novel ecosystems that differ from past species assemblages and their interactions. As discussed for Risk N14, habitat condition in some MPAs is a source of concern due to multiple pressures, notably fishing and pollution sources, which also acts to constrain opportunities, although the quality of monitoring is also problematic for progress monitoring.

#### 3.16.2.2 Effects of non-Government adaptation (N15)

New species can opportunistically become established in suitable areas through natural adaptation responses but knowledge of the extent to which this is occurring at local level is limited, although evidence of large-scale movements is established. In fisheries, there is evidence of species changes in catches and in some cases the sector has adjusted to take advantage of these changing opportunities, but this is also influenced by policy (quotas etc.) and consumer demand. The limited evidence (mainly informal and anecdotal) therefore suggests to us for this assessment that an *ad hoc* rather than co-ordinated response is occurring in response to new opportunities.

#### 3.16.2.3 Barriers preventing adaptation (N15)

Regarding fisheries, some new species are unfamiliar to UK consumers compared to traditional species which may limit demand for these new species despite increased numbers and the potential for sustainable harvesting compared to traditional species (The Grocer, 2019). Consumer concerns regarding environmental sustainability are also an issue for expansion through the aquaculture sector (Black and Hughes, 2017). For biodiversity conservation, there is often limited awareness of changing opportunities and sometimes a preference for attempting to conserve the status quo or to restore to a past position (Cochrane et al., 2016). Monitoring and data collection also remain poor, with 12% of stocks being of unknown status, with notable data limitations existing for nearly all elasmobranch (shark and ray) stocks, which means for fisheries, understanding of catches is poor due to low levels of effective monitoring at sea (State of Nature Partnership, 2019).

#### 3.16.2.4 Adaptation shortfall (N15)

Despite general government commitments for sustainable seas, there is only limited mention in current policy specifically related to new opportunities for marine species in UK waters. Furthermore, the shortfall in terms of non-governmental responses, either in the biodiversity or fisheries sector, indicates that further government intervention is required to support and guide required changes in collaboration with the diverse range of marine stakeholders. It is therefore concluded that the wide range of benefits that could be provided by this opportunity in the future will not be realised in the absence of additional government intervention. However, confidence is low due to the limited evidence available.

## 3.16.2.5 Adaptation Scores (N15)

**Table 3.50** Adaptation scores for opportunities to marine species, habitats and fisheries from changing climatic conditions

Are the opportunities going to be managed in the future?			
England	Northern Ireland	Scotland	Wales
No (Low confidence)	No (Low confidence)	No (Low confidence)	No (Low confidence)

## 3.16.3 Benefits of further adaptation action in the next five years (N15)

For marine biodiversity, there will be benefits from further investigation of new species in the context of changing species distributions, species interactions and habitat quality, especially in the context of the MPA network and therefore evidence-based recommendations for further development and enhancement of the network. As already highlighted (and also most notably for Risk N14), habitat condition is a crucial requirement to maximise new opportunities for biodiversity and current marine plans need to be further developed to recognise the key challenges for each priority habitat in the context of climate change adaptation, including their varying locations and viability as a coherent ecological network. Biogenic habitats are likely to be particularly important for realising opportunities due to their varied structure and habitat heterogeneity. These additional actions would also be consistent with further development of an ecosystems-based approach and a more systematic programme of research and monitoring that can facilitate an adaptive management approach that recognises the inevitable uncertainty and complexity in the marine environment. For fisheries, improved monitoring data would be beneficial on changing species movements and catches in order to better inform policy decisions on sustainable quotas for new species.

## 3.16.3.1 Indicative costs and benefits of additional adaptation (N15)

Many of the same options as identified for the risks to marine species and fisheries (risk N14) are also relevant for this opportunity, for realising the potential economic benefits. This includes capacity building in the industry, and the switch to an adaptive management approach for the fisheries sector, with a scale up in monitoring, scientific information and awareness raising, subsequently including this information in regular updates of fisheries policy (e.g. to set maximum catch potential for current species, include new species in policy) alongside awareness raising in the fishing sector. The CCC outcomes study (Watkiss et al., 2019) assessed that such an adaptive management strategy would have positive benefit to cost ratios, through the value of information and enhanced decisions taken. It is highlighted that there is a role for government in awareness raising for the fishing sector and for consumers, and enhanced monitoring of new species will require action by the public sector. Previous studies have also highlighted there is a need to target awareness and support in the fishing sector, to ensure opportunities are realised by small vessel operators, given their adaptive capacity will be lower (Frontier Economics, 2013).

## 3.16.3.2 Overall Urgency Scores (N15)

<b>Table 3.51</b> Urgency scores for opportunities to marine species, habitats and fisheries from changing climatic conditions				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	Further investigation	Further investigation	Further investigation	Further investigation
<b>Confidence</b>	Low	Low	Low	Low

There is a substantial likelihood that opportunities for marine species from changing climate conditions will continue to increase from present to future, although there is considerable uncertainty. However, much of the opportunity is unrealised, and there remains a significant adaptation gap according to the evidence available, particularly as there is a lack of evidence of both government-led and non-government action, unlike for some of the other opportunities in this chapter. We therefore recommend further investigation to improve information, awareness, and adaptive capacity for this topic, and hence to help structure more targeted policy responses.

Additional actions include:

- For biodiversity, further investigation is especially linked to further developing the role of marine protected areas to maximise opportunities to enhance biodiversity value (also including enhanced monitoring of species and habitat changes).
- For fisheries, opportunity assessments linked to improved data on current and projected movements of key species together with sustainable yield assessments.

## 3.16.4 Looking ahead (N15)

Improved monitoring data would be beneficial on species movements, habitat changes, and changing catches in fisheries (including shellfish) collated across all UK waters, and used to further develop model projections of future changes linked to UKCP18 and other data sources (including variables arranged according to ocean depth profile data).

## 3.17. Risks to marine species and habitats from pests, pathogens and invasive species (N16)

- There is considerable uncertainty around risks to marine species from pests, pathogens and INNS due in a large part to the scale and complexity of the marine environment.
- The risk magnitude for this topic is assessed as increasing from medium at present to high in the future, with low confidence.

- Despite current institutional risk assessment procedures providing some adaptive capacity to reduce risk, there remains an urgent need for more action to improve preparedness and address some of the key uncertainties.

## Introduction

This topic assesses pests, pathogens, and Invasive Non-Native Species (INNS; see Glossary for definitions) for the marine environment, which as highlighted previously is recognised for its high biodiversity value and its ecosystem services, including fisheries. As with Risk N14 and Risk N15, the scale and complexity of the marine environment means that considerable uncertainty remains for this risk, probably more so for pathogens. Nevertheless, based upon available evidence and drawing upon expert opinion (including horizon-scanning reports) we assess the magnitude of risk as increasing from medium (present) to high (future). The inter-connectivity of oceans and seas mean that the diffusion of pests, pathogens, and INNS is less constrained than on land, and the potential risk is considerably exacerbated by globalisation of trade and travel, particularly shipping.

The magnitude of risk increases in proportion to the degree of climate change, although the scale of this relationship is less certain, most notably due to the prospect of emerging risks especially at higher levels of climate change. The current institutional risk assessment procedures provide some adaptive capacity that can reduce this risk but there is an urgent need for more action to improve preparedness and address some of the key uncertainties. These co-ordinated actions, including through further international co-operation, should be consistent across the range of pests, pathogens, and INNS, regardless of previous policy distinctions (notions of ‘invasive species’ become rather more blurred in most marine environments, except for coastal habitats, and climate change challenges static concepts of ‘native species’).

It is very likely that EU-exit will have important implications for this risk through modified trade arrangements and associated adjustments to regulatory regimes, but details on these changes remains very limited at present. In addition, we have very limited information on how Covid-19 may modify this risk beyond a general increased public awareness of the severe consequences that arise from spread of pathogens.

### 3.17.1 Current and future level of risk (N16)

#### 3.17.1.1 Current risk (N16)

Existing evidence shows that the primary risk factor for initial establishment of harmful species and microorganisms in the UK is transport by ships, usually associated with international trade, and that the introduction of non-native species has increased in recent years (Cottier-Cook *et al.*, 2017). Climate change is therefore acting as an additional risk factor, principally through its influence on warming of seas, which can encourage establishment and spread of pests, pathogens and INNS at a magnitude not experienced previously. However, each problem species and micro-organism has its own climate sensitivity, either known or unknown (or only partly known), and it is also possible that genetic adaptation or mutation may alter that sensitivity.

In recent decades, UK shelf seas have warmed by ca. 0.1°C to 0.2°C/decade (with variations in different biogeographic zones), including stronger warming episodes during particular periods or years (e.g., 2014 – see Risk N14 for a more detailed discussion of recent warming trends). Our assessment is that incremental warming therefore provides increasing scope for establishment and spread of problem species and pathogens that are damaging to native biodiversity. Other climate-related factors, notably changes in salinity, may also be contributed to the risks, together with non-climate related stresses such as pollutant loads, turbidity, and ocean acidification.

This threat to biodiversity is evidenced by reports of increasing problems with INNS and pathogens including from viruses, fungi and bacteria. For example, fish gill disease is a notable problem for aquaculture, and this can occur from parasite, virus, or bacterial sources, with elevated temperatures and high salinity noted as exacerbating risk factors (Boerlage *et al.*, 2020). Increasing risks from problem species and pathogens have also been identified through their importance for human health protection (e.g., *Vibrio* bacteria in shellfish) and threats to commercially important marine species, especially bivalve shellfish (e.g., oysters) (Danovaro *et al.*, 2011; Bresnan *et al.*, 2020).

An investigation of eight target INNS in England and Wales showed 209 records of one or more of these species in MPAs, and that three of the INNS (*Undaria pinnatifida*, *Sargassum muticum*, and *Corella eumyota*) had led to changes in community composition (Macleod *et al.*, 2016). Evidence also suggested potential changes in community structure could impact upon on some MPA intertidal and subtidal biogenic features, including reefs, subtidal macrophyte-dominated sediment, seagrass beds and native oysters. A matrix tool using a 'traffic light' system based on MPAs features, identifying those susceptible to (or already colonised by), defined 16 of the 112 MPAs as higher risk (i.e., 'red'), in that they contained five or more suitable features and environmental conditions for the establishment by one or more of the eight INNS.

Major pathways for the arrival of invasive non-native species (INNS) in UK waters are on the hulls of ships, through the release of ship ballast water, from aquaculture-related introductions, and as stowaways on fishing or other mobile equipment. Shipping represents the main transport mode for world trade and with increased globalisation the scale of shipping transport has further increased in recent decades. For these reasons, the level of risk is increasing. Ports typically become the initial focal areas for introduction of INNS but they can also become established at less obvious locations: for example, one notable INNS, the gulf wedge clam, was recently discovered at a remote site in Lincolnshire (Willing, 2015). Although not known for certain, the cause of the introduction of Pacific oyster on the east coast of Scotland has been proposed to be from ballast water, as there had been no aquaculture ventures for the species in that region (Smith *et al.*, 2014). Once established, problem species usually become very difficult to eradicate in the marine environment, and hence can be even more problematic than terrestrial or freshwater INNS. For this reason, prevention is an even more important strategy.

There are also some indications that the increased presence of artificial structures in the marine environment, including platforms for offshore wind farms, or artificial reefs, may be associated with increased colonisation by non-native species due to the different substrates (e.g., Herbert *et al.*,

2017, Coolen *et al.*, 2020). At present, however, the evidence is not yet conclusive whether this is increasing the risk from damaging invasive species.

In addition to observation records of problem species already present in the UK, horizon scanning provides a valuable tool to consider new INNS that may arrive both at present and in the future. Following such a methodology and including a risk assessment based upon scale of potential invasiveness (i.e., disruption to native ecosystems), a previous exercise found that eight marine species are included in a list of the top 30 most invasive species in Great Britain (Roy *et al.*, 2014a). These include Asian shore crab, brush-clawed shore crab, American comb jelly, veined rapa whelk, cauliflower sponge, rough agar weed, American lobster, and Japanese sting wrinkle (the latter two species being highlighted on Defra's priority eradication list).

More recently, an expert-based horizon scan of invasive alien species has been completed for the island of Ireland (Lucy *et al.*, 2020), finding that crustacean species (freshwater and marine) were the taxa most commonly identified as a threat due to their multiple pathways of introduction, their ability to act as ecosystem engineers and their resulting high impacts on biodiversity. The most likely marine invader was identified as warm-water barnacle (*Hesperibalanus fallax*), with pom-pom weed (*Caulacanthus okamurae*), American razor-clam (*Ensis leei*), Brush-clawed shore crab (*Hemigrapsus takanoi*), the sponge *Celtodoryx ciocalyptoides*, and Asian shore crab (*Hemigrapsus sanguineus*) also identified in the top 40 overall threats. Some of these INNS have already been recorded in south west England and Wales, therefore the risk of spread to Northern Ireland is high and they are highlighted as clear 'door-knocker' threats. Similar horizon scanning assessments of risk on a 10-year timescale have also been conducted for the EU, including the Atlantic biogeographic region where the UK is located (Roy *et al.*, 2019; Tsiamis *et al.*, 2020).

Diseases are not uncommon in the marine environment and may impact marine ecosystems by influencing community structures, age distributions, trophic interactions, hydrodynamics, and biotic structures. The relationship between climate change and pathogens is less well understood compared to existing pest species and INNS and may also be occurring through indirect rather than direct climate-related factors, as, for example, through changing host-pathogen relationships (Harvell *et al.*, 2009).

Climate-related range shifts may therefore occur in both hosts and pathogens which therefore requires a multi-factorial risk assessment, identifying the possibility for major unknowns and emergent risks. For example, the spread of some viruses may be associated with the movement of host animals due to the changing opportunities provided by ocean warming. This may include the morbillivirus group of pathogens, amongst which the Phocine morbillivirus (phocine distemper virus: PDV) has been prominent in causing recent seal deaths in European waters, particularly in Denmark (Duignan *et al.*, 2014). Other mammals can be infected by similar viruses, include dolphins and otters, therefore the consequences for marine biodiversity from a large-scale outbreak may be high where mixing of different animal communities is more common. Attribution of such outbreaks to climate change is extremely difficult due to the variety of possible cause-effect relations. It is possible that warming may have accelerated development of the pathogen. Alternatively, shifts in land-use or rainfall patterns can increase terrestrial pathogen flow to the coastal zone, increasing marine mammal exposure.

Viral infections are also known to affect other taxa, including Atlantic salmon. However, by comparison to farmed species, the impacts of diseases on wild marine fishes are extremely difficult to enumerate, owing largely to the challenges of studying highly mobile organisms in open seas where direct observation is less feasible unless through limited sampling or liaison with the fishing industry.

Climate change may also act to decrease some pathogens, although again evidence is very limited. In reviewing disease incidence across a range of taxa, Tracy *et al.* (2019) noted decreasing reports of incidence for fishes, but as these have incurred human-induced population declines and reduced population densities this may be acting to reduce disease rather than warming seas.

### 3.17.1.2 Future risk (N16)

The scientific consensus is that risks from pests, pathogens and INNS will increase in proportion to the degree of future additional marine warming but there is considerable uncertainty on how this will occur (e.g., Donovaro *et al.*, 2011; Burge *et al.*, 2014; Mellin *et al.*, 2016; Rinde *et al.*, 2017). Warming of UK shelf seas is projected to continue to 2100 and beyond with most projections simulating increases of between 0.25°C and 0.4°C per decade, but with regional biogeographic differences and the greatest warming in the Channel and southern North Sea (see Risk N14).

In addition, several of the other stressors identified above are likely to continue (as discussed in more detail for Risk N14), including ocean acidification and changes in salinity levels due to stratification and modification of currents, increasing the vulnerability of marine organisms to invasive species or pathogens. Furthermore, at higher magnitudes of climate change there is an increasing possibility of emergent unknown risks as existing marine ecosystems are increasingly disrupted and dispersed to produce new biotic interactions and novel ecosystems.

Socioeconomic risk factors will also strongly influence the magnitude of risk, including future changes in global trade patterns, ocean pollution, and further expansion of aquaculture. Regarding trade patterns, increased shipping from regions such as SE Asia, Africa and South America is likely to further increase exposure to new problem species and pathogens. The key issue will then be the degree of refinement and enforcement of biosecurity procedures, especially at the most vulnerable locations such as ports and harbours.

Information on the changing pattern of risk is primarily available for problem species and pathogens that are already prominent in the UK or Europe, such as the Pacific oyster. In addition to those INNS identified above, other known problem species that could further spread in the UK include Chinese mitten crab, which has a lifecycle that shifts between marine and freshwater environments, and the carpet sea squirt.

Regarding Pacific oyster, this is an introduced species that has already become established on the Channel coast aided by warming waters in recent decades, with sporadic colonisations established elsewhere in the UK, including as far north as the Firth of Forth (Scotland: Smith *et al.*, 2014). A

continuing trend towards warmer seas mean it is likely to become successfully recruited on an annual basis in south-west England, Wales and Northern Ireland by 2040 (Rinde *et al.*, 2017; see also 'Thresholds' section below). This has important implications for biodiversity because as an 'ecosystem engineer', the Pacific oyster can transform intertidal systems resulting in a more homogeneous habitat impacting especially on native bivalves such as mussels, cockles and the native oyster, in addition to blue mussel aquaculture locations (Jones *et al.*, 2020). Negative impacts may also extend to intertidal bird species such as Dunlin, red knot, common gull and oystercatcher which use mussels as a food source (Waser *et al.*, 2016). Conversely, there may be some potential benefits such as for improving water quality, wave attenuation for flood defence, and an additional food supply, although the actual trade-offs between benefits and losses will depend on the density of colonies and local site factors (Herbert *et al.*, 2016).

Regarding pathogens, there are many unknowns, notably changing host-pathogen relationships, range shifts (hosts and pathogens), and increasing disease frequency and virulence due to increasing thermal stress on host species and climate-change related suppression of host immune responses (Burge *et al.*, 2014). In addition, there is limited data for most biodiversity-related pathogens which constrains modelling of future patterns of change.

A further concern regarding aquaculture, which is planned to further expand in the UK (Black and Hughes, 2017), is the impact of antimicrobial resistance (AMR) because antibiotics are commonly used in feedstuff to control bacterial infections. Meta-analysis across several countries (including the UK) has shown an association between aquaculture-related AMR and climate warming: the causes of this relationship are poorly understood but likely to involve the increased virulence of pathogens at higher temperatures and associated increased use of antimicrobials to protect against fish mortality, hence the rise in AMR (Reverter *et al.*, 2020).

#### 3.17.1.3 Lock-in (N16)

There are potential lock-in risks associated with continuing to develop international trade without a full assessment of the changing distribution and consequences from INNS and pathogens. Once a problem species is established in the UK, eradication often becomes extremely difficult (more especially in marine environments, as noted above), hence the initial introduction (either deliberate or inadvertent) can result in a form of lock-in whereby the natural ecosystem is potentially irreversibly modified with potential consequent effects on biodiversity, ecosystem functioning and ecosystem services, and for ecosystem-based adaptation. This potential for irreversibility may be increased with warmer seas and therefore for the risk to become locked in for the future.

#### 3.17.1.4 Thresholds (N16)

Climate thresholds are important in establishment of INNS and likely to be also key factors in the virulence of pathogens and in host-pathogen relationships, especially for sea temperature and also salinity. The relationship of threshold effects with species physiology has been identified as a key issue for further research (Monaco and Helming, 2011). The CCC thresholds project (Jones *et al.*, 2020) investigated temperature thresholds for establishment and spread of the Pacific oyster as a case example (using a threshold for spawning of 825 degree-days for a daily mean bottom

temperature of 10.55 °C). This analysis showed a potential for range expansion across much of the UK by the 2080s as temperatures increase, in some locations potentially threatening native oysters, with the rate of change depending on climate change projection. Greatest gains in suitable area were observed in England, which was driven predominantly by large areas of the shallow North Sea around Dogger Bank becoming suitable. Scotland saw the largest percentage increase in suitable area, driven by large increases in suitable habitat in the Inner Hebrides. As noted above this is an example where expansion may be perceived as an opportunity by one sector (shellfish aquaculture) and a risk by another sector (biodiversity), in addition to having regional implications in terms of whether the invasive species is already established.

#### 3.17.1.5 Cross-cutting risks and interdependencies (N16)

In addition to biodiversity there are important interactions with fisheries (including aquaculture) and with human health, livelihoods, and well-being. As noted above regarding the Pacific oyster, INNS can also potentially involve some benefits through enhancement of some ecosystem services but there are often difficult trade-offs against native biodiversity and these trade-offs may also vary with location. The spread of pests can also have important implications for marine heritage, as exemplified by increased problems reported with the impact of shipworm (Harkin *et al.*, 2020).

The risk of pests, pathogens and INNS may be increased due to pressures on native biodiversity that both reduce the competition that problem species will experience, hence facilitating their spread, and also make native biodiversity more susceptible to pathogens such as through weakened immune system responses. In addition, it will be important that the risk of pests, pathogens and INNS are included in habitat enhancement, recovery, restoration and creation projects, and associated plans for an expansion in nature-based solutions. For example, native oyster restoration, seagrass restoration and saltmarsh creation and other similar schemes (as discussed in Risks N14 and N17), which also require re-introduction of native species (either sourced from the wild or from hatcheries/farms), will also require increased awareness of the inherent risks from the spread of parasites, pathogens and INNS as guided by codes for best practice in licensing obligations (e.g., in Scotland, the Scottish Code for Conservation Translocations: National Species Reintroduction Forum 2014).

It is also possible that increased runoff and discharge of pollutants from land (both point sources such as sewerage systems and diffuse sources as from agriculture) due to heavier rainfall events could increase risk from pathogens, as is occurring with excess nutrient runoff and Harmful Algal Blooms in coastal waters (Bresnan *et al.*, 2020). In addition to biodiversity impacts this can have adverse impacts for fisheries, especially for shellfish.

#### 3.17.1.6 Implications of Net Zero (N16)

There are potential implications through the impact on key species and habitats that deliver carbon sequestration benefits ('Blue Carbon'), although very little evidence is available. In addition, there may be indirect effects through impacts on fisheries and aquaculture, both of which are seen as

low-carbon food sources compared to some other alternatives. However, presently the marine sector remains a less-developed component of the Net Zero scenario.

In the context of plans for further expansion of renewable energy, as also noted above there is some evidence to suggest that the platforms used for new offshore wind farms may be preferentially colonised by non-native species due to the different substrates in the platforms. Although evidence is currently limited, the risk is that platforms act as ‘stepping stones’ for expansion of these non-native species.

### 3.17.1.7 Inequalities (N16)

No specific societal inequalities associated with climate change were identified in relation to risks marine species.

### 3.17.1.8 Magnitude scores (N16)

<b>Table 3.52</b> Magnitude scores for risks to marine species and habitats from pests, pathogens and invasive species					
<b>Country</b>	<b>Present Day</b>	<b>2050s</b>		<b>2080s</b>	
		<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>	<b>On a pathway to stabilising global warming at 2°C by 2100</b>	<b>On a pathway to 4°C global warming at end of century</b>
<b>England</b>	Medium  (medium confidence*)	High  (low confidence)	High  (low confidence)	High  (low confidence)	High  (Low confidence)
<b>Northern Ireland</b>	Medium  (medium confidence*)	High  (low confidence)	High  (low confidence)	High  (low confidence)	High  (Low confidence)
<b>Scotland</b>	Medium  (medium confidence*)	High  (low confidence)	High  (low confidence)	High  (low confidence)	High  (Low confidence)
<b>Wales</b>	Medium  (medium confidence*)	High  (low confidence)	High  (low confidence)	High  (low confidence)	High  (Low confidence)

Notes: Magnitude categories based on expert judgement and assessed in terms of existing or expected impacts on biodiversity (including viable metapopulation sizes), ecosystem functioning, and ecosystem services (including fisheries but excepting carbon storage – Risk N5). This approach is also followed because indicators based upon species numbers or habitat area are only crudely indicative of systemic risks. Risk magnitude is assessed to increase from medium at present to high

in the future under all climate projections due to the high climate sensitivity of marine organisms and micro-organisms associated with this risk. Confidence is medium for present risk but low for the future because the full scale of this risk remains to be established and there is an increased prospect of new emergent risks.

*\* Confidence is low for pathogens.*

### 3.17.2 Extent to which current adaptation will manage the risk (N16)

#### 3.17.2.1 Effects of current adaptation policy and commitments on current and future risks (N16)

##### 3.17.2.1.1 – UK wide

The risk topic is owned by Defra, the Scottish Government, Welsh Government and DAERA. The general policy context for management of pests, pathogens, and INNS is provided in Risk N2, including relationships with international agreements (Bern Convention etc.) and other larger-scale international initiatives. Strategies to control and eradicate INNS were also a commitment made by the UK Government to the 2020 UN Aichi Targets for Biodiversity.

In addition to these general requirements, the marine environment also requires more specific aspects of risk management in relation to climate change adaptation. The general marine policy context is covered in Risk N14. Regarding this specific risk, the interconnectivity of the marine environment means that prevention is the most effective control strategy as measures to control spread once established can be very difficult to implement effectively in marine waters, especially for INNS.

The Great Britain INNS strategy covers marine environments but does not include non-native genetically modified organisms, bacteria or viruses, nor animal or plant diseases (which are included in the UK Biological Security Strategy), although it does include invasive species that carry disease. The GB Non-native Species Secretariat conducts risk assessments, and monitors incidents and outbreaks. Risk assessments are now being further developed through horizon scanning of future risks based upon changes in trading relationships.

In May 2019, the UK Government published its comprehensive pathway analysis (as required then by EU Regulations) which identified three priority pathways for controlling INNS in the marine environment: (i) hull fouling, (ii) ballast water, and (iii) contaminants of aquaculture animals. Further measures to provide increased prevention have been identified including: (i) ensuring vessels arriving or leaving UK waters have stringent hull cleaning and (ii) all ships to have a ballast water management plan. The UK Government is committed to, but yet to ratify, the International Convention for the Control and Management of Ships' Ballast Water and Sediments ('Ballast Water Management Convention') as associated with the increasing threat of invasive species. Ratification was expected during 2020 but was delayed due to the Covid-19 pandemic (on the grounds that the priority was to maintain the flow of essential goods) and is therefore now expected to follow a process of consultation and ratification once the Covid-19 crisis has been resolved (Maritime & Coastguard Agency, 2021).

#### 3.17.2.1.2 England

The second National Adaptation Programme and the 25YEP for England make related commitments to continue with the GB INNS Strategy and to review it in the context of climate change but no detailed actions are provided for the marine environment beyond a continuation of these existing policies.

#### 3.17.2.1.3 Northern Ireland

Northern Ireland collaborates with the Irish Republic on an all-Ireland approach to INNS, which includes the threat from marine species. There are also plans for further integration of Northern Ireland into a UK Non-native Species Secretariat. The 'Invasive Alien Species Strategy for Northern Ireland' aims to address knowledge and awareness gaps, and minimise introductions and spread of INNS, whilst also aiming to eradicate and control existing problem species, also through a partnership and capacity building approach. The Marine Plan for Northern Ireland (2018), which could also provide a strategic pathway to build adaptive capacity for this risk, is yet to be adopted by government.

#### 3.17.2.1.4 Scotland

The second Scottish Climate Change Adaptation Programme (SCCAP2) identifies a similar continuation of existing commitments and that Marine Scotland will continue to keep under review how it approaches INNS management, including partnership working to minimise the threats posed by INNS. The Marine Plan for Scotland also establishes a general policy framework for these actions linking with biodiversity, fisheries and other sectors. The SCCAP2 also notes a new potential indicator for the future to record absence of INNS as complement to the current indicator on presence of INNS.

#### 3.17.2.1.5 Wales

In Wales, the latest Adaptation Plan also makes a commitment to further monitoring and planning for marine INNS, including the INNS Portal which was launched as part of the National Biodiversity Network (NBN) Atlas Wales in November 2018. The Welsh National Marine Plan (2019) defines general marine policy guidance for the next 20 years. This includes plan policies that support Good Environmental Status through the management of marine INNS, requiring that proposals should demonstrate how they avoid or minimise the risk of introducing and spreading INNS. Although not directly targeting climate risk as the cause of INNS, the Welsh National Marine Plan does state the support of climate change adaptation and resilience as one of its 13 main objectives.

#### 3.17.2.2 Effects of non-Government adaptation (N16)

The responsibility to report and manage incidents remains with the landowner, which depends on the awareness, knowledge and capacity of an individual or organisation, and therefore can be rather variable, without further specialist support. Similarly, ship owners and crew have variable knowledge of the risks and therefore do not always manage them according to best practice (e.g., ballast water release).

Partnership working and knowledge exchange to increase awareness of risks is promoted and supported. For example, the Wales Invasive Non-native Species Group, WaREN, was formed to help identify INNS priorities and resolve issues relevant to Wales.

### 3.17.2.3. Barriers preventing adaptation (N16)

Changes in the distribution of pests, pathogens, and INNS can be rapid and unexpected, linked not only to climate factors, but also changes in globalisation, especially shipping routes. Therefore, awareness of the changing risks and capacity to respond quickly are crucial, although this often remains under-developed (Giakoumi et al., 2019). Further work on the disbenefits and benefits from different non-native species (including those defined as INNS) is also required to achieve a consistent position; in some cases, the non-native species may have advantages for commercial extraction or habitat restoration that need to be balanced against disbenefits through a structured risk assessment and options appraisal (Giakoumi et al., 2019). A notable example, as described above, would be conflicting attitudes towards the spread and establishment of Pacific oyster in the UK, including as a threat to native oyster populations. Port and harbour authorities (including marinas) are key organisations together with informal public networks (local angling networks, fishing operators, divers etc.). In addition, the role of local government can be crucial, although resources are not always available to cover this role, and therefore response capacity can be quite variable.

It should also be emphasised that although some established pest species are already well known, the occurrence of INNS and pathogens has a strong stochastic and therefore emergent risk component, meaning that there are limits to forecasting and prediction, even with enhanced horizon-scanning capability. With regard to climate change, a challenge for knowledge exchange and improved awareness is that the role of climate factors is not fully understood, especially for pathogens. This additional element of unpredictability, although it can be partly addressed by improved international collaboration and data sharing on changing risk parameters, effectively requires a multi-tiered approach to contingency planning, including through scenario exercises, so that even for 'surprise' introductions there is a protocol for control and containment.

### 3.17.2.4 Adaptation shortfall (N16)

In summary, our view is that the main emphasis of these policy commitments is on continuation of existing policies and there is little extra detail regarding the additional risks from climate change and specifically for the marine environment, although references are starting to be made in key documents. In addition, it is not yet clear how plans for continued international collaboration (including with the EU) will be taken forward following EU-exit, including for surveillance, monitoring and horizon scanning.

While there is some evidence of non-government actions, addressing this risk requires specialist support and guidance, more especially to identify and communicate new and emerging risk species and micro-organisms. This is a topic that requires a co-ordinated approach, linking science and policy, and with the capacity to anticipate and regularly update the changing nature of the threats.

Based on this, current adaptation is assessed as insufficient to manage future risks down to a low level. We also note that due to evidence constraints that confidence is low, especially as evidence on the effectiveness of adaptation options remains rather limited.

### 3.17.2.5 Adaptation Scores (N16)

<b>Table 3.53</b> Adaptation scores for risks to marine species and habitats from pests, pathogens and invasive species			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.17.3 Benefits of further adaptation action in the next five years (N16)

As identified above, pest species and INNS, once established, are very difficult and costly to eradicate in the marine environment. Similarly, for marine pathogens, land-based management methods that are currently employed of quarantining, culling, or vaccinating are not successful. This means that enhanced control measures through biosecurity regulations and best practice have the greatest benefits in reducing risk, complemented by improved forecasting of outbreaks to provide additional focus. Forecasting is also associated with requirements for strong systems of international monitoring and surveillance to provide updated data on problem species and pathogens. Improved data and forecasting capability would also allow further investigation of the role of climate-related parameters in risk assessment. Enhanced prevention through policy co-ordination will also be crucial, notably further steps to embed biosecurity in national and regional marine planning in relation to climate change, and also stronger incorporation of biosecurity planning as part of the consenting process for relevant marine sectors.

At a more local level, there are very likely to be benefits from enhanced engagement and knowledge exchange with community groups and practitioners. For example, NRW have developed collaboration with the Welsh Fishermen's Organisation to record INNS.

#### 3.17.3.1 Indicative costs and benefits of additional adaptation (N16)

There is some information on control (adaptation) costs, which can be considered either an impact or reactive adaptation. These can involve high costs. For example, the Carpet Sea Squirt has spread to the UK and there have been a number of recent outbreaks in ports. Williams et al (2010) estimated the cost of eradication of the UK population from currently affected marinas at £2.4 million, but if this species spreads UK-wide, the overall cost of eradication could rise to £72 million. Hence, the total eradication cost would be very much higher. It should also be noted that these are cost-based measures so do not capture people's willingness to pay to avoid marine INNS. More generally, this indicates that once established, managing invasives can be costly. Given that these may spread as a result of climate change, and the need for co-ordinated provision of information,

there would seem to be a case for an expanded role for Government intervention to provide enhanced monitoring and surveillance and early response. Evidence on the economic justification for such a scale up is available for terrestrial invasives and suggests high benefit to cost ratios (Moran et al., 2013) and it is assumed similar ratios would be applicable for the marine environment.

### 3.17.3.2 Overall urgency scores (N16)

<b>Table 3.54</b> Urgency scores for risks to marine species and habitats from pests, pathogens and invasive species				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Low	Low	Low	Low

Given the projected increase in risk magnitude for this topic (from medium at present to high in the future across the UK), together with the lack of sufficient recognition of climate change in current policy frameworks and risk assessment procedures, a 'More Action Needed' urgency score has been assigned to this topic. The scale and complexity of the marine environment means that considerable uncertainty remains for this risk, indicating that a twin-track approach of improved contingency-based risk management measures and further research to address key knowledge gaps would likely to be most useful. As part of this enhanced capability, the use of scenario planning, guided both by evolving knowledge and additional 'what-if' scenarios, would have added value in enhancing knowledge exchange between science, policy, and practitioners.

Actions include:

- Collect long-term data to better understand host-pathogen interactions, and how outbreaks and disease syndromes are affected by extreme events, climate variability, and climate change.
- Improve surveillance, horizon scanning, and modelling capability for INNS and pathogens, including through international collaboration.
- Improve biosecurity awareness and promotion of best practice across all relevant sectors including in habitat enhancement, recovery, restoration and creation.
- Enhanced emphasis on prevention measures as crucial for marine INNS, including implementing pathway action plans for priority pathways identified through risk assessments.
- Improve public awareness, including further use of citizen science.
- Improve understanding of factors that contribute to disease-resistant organisms.
- Improved understanding and contingency planning for emergent risks, especially for novel pathogens.

#### **3.17.4 Looking ahead (N16)**

As above, the next CCRA would benefit from improved large-scale data on the dynamics of marine INNS and pathogens, complemented by scenario modelling capability to further test and investigate the evolving interaction of climate change relationships with non-climate risk factors (international policy, trade, demographics etc.).

### **3.18 Risks and opportunities to coastal species and habitats due to coastal flooding, erosion, and climate factors (Risk N17)**

- The magnitude of risk to coastal species and habitats from changing climatic conditions is projected to increase from medium at present to high in the future. This will be especially influenced by the rate and magnitude of sea level rise, which more recent projections including UKCP18 suggest may be higher than assumed for CCRA2.
- Although negative risks predominate, there are also opportunities for habitat creation and species gains depending on habitat type, location, magnitude of climate change and sea-level rise, and management response.
- Overall progress on managing this risk remains limited, although there are increasing numbers of positive local examples that can be highlighted. Nevertheless, significant barriers remain and for much of the coast there is an increased risk of lock-in to an unsustainable future.
- Evidence indicates that adaptation through effective implementation of nature-based solutions, including managed realignment and habitat restoration, can reduce the risks and provide multiple benefits and potential opportunities.
- Adaptation strategies need to be designed to be more flexible and robust against the wider range of climate change projections, and especially for higher rates and magnitudes of sea-level rise.

#### **Introduction**

Coastal habitats occur at the terrestrial/marine interface including both intertidal and supratidal environments, notably saltmarsh, machair, vegetated shingle, sand dunes, saline lagoons, and sea cliffs. As an island nation, the UK is internationally recognised for its coastal habitats and species, and these provide a major contribution to national identity. In addition to their biodiversity value, these habitats provide many ecosystem services, such as flood and erosion protection, fisheries (especially as nursery areas), climate regulation (through carbon storage), tourism and leisure opportunities, and through interaction of the natural environment with cultural heritage. The UK National Ecosystem Assessment cited one study (COREPOINT, 2007) that assessed the total value of coastal ecosystem services as worth at least £48 billion, whilst the Office for National Statistics (2016) prototype methodology for ecosystem accounts provided an indicative net present value over 50 years of £22.7 billion based upon those services that are more easily quantified.

Although policy may define the issues separately (as suggested by the initial nominated list of risks for CCRA3), this assessment covers both coastal erosion and flooding together. By doing so, we

recognise that these are inter-related and co-evolving processes, and that changes in one type of hazard can affect the other and the resultant risks. Erosional processes modify coastal morphology and therefore flood risk. For example, this can lead to a breach in a shingle or sand barrier, or loss of a beach or saltmarsh, which can lead to flooding. Similarly, from an alongshore perspective, changing patterns of erosion or accretion may exacerbate or reduce flood risk down-coast. High water levels that cause flooding can also significantly alter patterns of erosion through changes in hydrodynamic forcing with potential threshold effects. Assessing risks from erosion and flooding together is therefore consistent with moves towards developing an integrated systems approach for adaptive risk management (Dawson *et al.*, 2015; Pollard *et al.*, 2019).

Although the dominant effect of climate change may be negative, we also recognise there may also be positive aspects for some habitats and species, especially when erosion is accompanied by accretion and habitat creation in other locations, highlighting the importance of integrated coastal zone management. In the context of biodiversity, it is also necessary to consider other climate-related changes in coastal areas, notably changes in temperature and precipitation, and potentially wind, which may increase the vulnerability of some habitats and species.

We assess this risk as increasing from medium (present) to high in future, this being especially influenced by the rate and magnitude of sea level rise (which the most recent assessments indicate may be at a higher rate/magnitude than assumed for CCRA2 – see Chapter 1: Slingo, 2021). At present adaptation responses are inadequate to match the scale of the risk nor to realise potential opportunities for habitat creation, and we also recognise significant lock-in risks. Therefore, as with CCRA2, this topic remains a priority for more policy action.

Our assessment of risk magnitude is supported by good evidence on the scale of present-day impacts and by using modelling and extrapolation of present risk to infer future changes which increase in proportion to climate-change related drivers, notably sea-level rise. Evidence of the effectiveness of current adaptation in moderating the risk is more limited, although often available by default through present-day residual impacts which show a significant adaptation shortfall. Nevertheless, there is also available evidence that adaptation options such as managed realignment and habitat restoration, if implemented appropriately for the location, can have a key role in reducing the risks and providing multiple benefits and potential opportunities, although more research and evidence is also required here to better support adaptive management in practice. The existing level of implementation of managed realignment and habitat restoration is insufficient even at present rates of sea-level rise, and very small considering historic losses. Further action and supporting research are also required on the implementation of more strategic risk management approaches that integrate realignment or rollback options with structural defences that will inevitably continue to be required at some locations, but which also have an impact on the adjacent coastline. With appropriate support, Shoreline Management Plans can provide an ongoing science-policy mechanism for taking forward adaptive management solutions, including further appraisal of different adaptation pathways based on alternative climate change scenarios.

Both EU-exit and Covid-19 are very likely to further influence climate change risks, most notably in terms of indirect effects such as delays to adaptation actions and progress monitoring, but at present we have no evidence for this.

### 3.18.1 Current and future level of risk or opportunity (N17)

#### 3.18.1.1 Current risk (N17)

##### 3.18.1.1.1 Sea-level rise and other Climate-related factors

As highlighted in Chapter 1 (Slingo, 2021), evidence suggests an acceleration in sea-level rise over recent decades (global mean acceleration  $\sim 0.1 \text{ mm/yr}^2$ : Veng and Andersen, 2020) such that the trend in absolute mean sea level 1993-2019 for the UK coastline based on satellite data is now generally 2.0-2.5 mm/yr (slightly higher to the north and east). Local patterns of sea level rise relative to the land (as measured by tide gauge data) are also influenced by distinctive local and regional secular effects, in addition to land movements (generally subsidence in the south or uplift in the north). These variations complicate an overall assessment of risk, but the general pattern is for an increased rate of relative sea-level rise throughout the UK coastline (at least 2-3 mm/yr), which is acting to further increase the flood risk for low-lying habitats and their dependent species. In addition, as reported in previous CCRAs, estuaries and other local coastal features can have their own patterns of faster and slower water level rises due to phenomena such as amplification of the 18.6-year lunar cycle, or due to local fluvial, morphodynamic and hydrodynamic interactions (Wang and Townend, 2012; Robins *et al.*, 2015).

There is also evidence for an increase in North Atlantic storms at the end of the 20th Century, linked to concurrent changes towards a more frequent positive winter NAO, and this can be particularly important factor for erosion risk, depending on location. Using a 69-year numerical weather and wave hindcast, Castelle *et al.* (2018) found significant increases in NE Atlantic winter-mean wave height, variability, and periodicity, also showing strong correlations with the NAO index. Similarly, review of an array of evidence sources by Wolf *et al.* (2020) also identified an apparent trend towards both increased storminess and increased wave heights in the NE Atlantic, although also noting considerable interannual and interdecadal variations.

##### 3.18.1.1.2 Coastal Erosion and Accretion

Previous CCRAs have synthesised evidence that a significant proportion of the coastline of the UK is currently suffering from erosion; for example, one estimate placed this proportion at 17% (EUROSION, 2004). In England and Wales, 28% of the coast has been identified as experiencing erosion  $>10 \text{ cm}$  per year (Burgess *et al.*, 2007). The National Coastal Erosion Risk Mapping Project (NCERM: Rogers *et al.*, 2008) found that 42% of England and Wales is at risk from coastal cliff erosion, of which 82% is undefended. When including coastal floodplains, beaches, barriers, and intertidal areas, including areas protected by artificial defences, the proportion at risk increases to 68% (FutureCoast, 2002). Over the longer term, investigation of chalk cliff erosion in southern England has shown an increased erosion rate in recent centuries, which is attributed to reduced sediment supply and thinning of beaches (Hurst *et al.*, 2016). Assessment of coastal SSSIs in England assumed to be at risk from erosion from the present up to 2025, based upon extrapolation of historic erosion rates using NCERM data, produced a central estimate of 600ha (50% likelihood) and an upper range estimate to 800ha (5% likelihood).

In Scotland, 78% of the coast is considered 'hard or mixed' (i.e., with low erosion rates), 19% is 'soft/erodible', whilst 3% has artificial defences (Hansom *et al.*, 2017). As noted by previous CCRAs, evidence shows that the notion that postglacial isostatic land uplift in northern Britain would mean that coastal impacts associated with eustatic sea-level rise would be a lesser risk factor for Scotland (and Northern Ireland) is not tenable, and relative sea level rise is now dominant throughout the UK. The Dynamic Coast project has affirmed the implications of this changing hazard by using shifts in the mapped position of the MHWS (Mean High Water at Spring Tides) line, finding that, since the 1970s, 77% of the soft/erodible coast in Scotland has remained stable, 11% has accreted seawards and 12% has eroded landwards (Hansom *et al.*, 2017). Using a longer time interval, comparisons of the post-1970s period with the late 19<sup>th</sup> century suggest a reduced extent of accretion (by 22%) in Scotland, a 39% increase in the extent of erosion, and a doubling of average erosion rates from 0.5 to 1.0 m/yr (and similarly, average accretion rates have almost doubled to 1.5 m/yr). The larger shifts in the balance of erosion and accretion are found particularly in the east coast and Solway Firth area, although some localised areas on the west coast can also be distinguished, notably for the Western Isles, which are important for their distinctive machair habitats.

For Northern Ireland, there is generally less detailed information on coastal change. However, it has been estimated that ca. 20-30% of the coastline is either eroding or at risk of erosion (EUROSION, 2004; McKibben, 2016), and that 32% of the coast has some form of protection (Cooper *et al.*, 2016).

Erosion has had both direct effects on exposed undefended coastlines and indirect effects when associated with hard defences. In the latter case, as highlighted in past CCRAs, the indirect effect has been 'coastal squeeze' whereby erosional impacts have been concentrated on the intertidal zone to seaward of defences causing habitat loss. Around 72% of the intertidal flats and marshes in England are considered at risk of coastal squeeze because of the presence of landward sea defences, whilst in Wales, 44% of the coastal Natural 2000 sites have been flagged as being at risk from coastal squeeze (Miles and Richardson, 2018); no equivalent indicators for coastal squeeze are yet available for Scotland and Northern Ireland. CCRA2 also noted the severe effects of erosion that have occurred during severe stormy periods, such as winter 2013/2014, which can have a long-term legacy in terms of habitat loss.

Another less-reported type of coastal squeeze is occurring in those cliff-top locations that have distinctive maritime grasslands of high biodiversity value. These grasslands are often bordered inland by agricultural land and whilst the farmland boundary has tended to remain in the same local position, erosion of the cliffs has acted to reduce the area of maritime grassland habitat, although no national-level figures are currently available for the extent of this loss.

Areas of accretion which represent habitat creation opportunities are more localised but include ness features and accretion associated with sediment sinks in estuaries (e.g., The Wash; Humber estuary; Firth of Tay; Dee estuary). Currently most of the coast has a constrained sediment budget because of the high proportion that is defended, although, as noted above, the evidence does also suggest that unprotected areas (e.g., soft cliffs) may be experiencing increased erosion rates. The recycling of eroded sediments to supply accretion zones is complicated by local and regional tidal dynamics and wave-driven longshore drift, with some of the finer-grained sediment actually being

transported over large distances (e.g., southward on the North Sea coast, including to sediment sinks offshore from the Netherlands and in the German Bight).

#### 3.18.1.1.3 Coastal flooding

Flooding affects coastal species and habitats through frequency of saline inundation. This inundation may be temporary as a consequence of episodic extreme high-water levels (e.g., from a storm surge event) or permanent (e.g., following a planned/unplanned breach of natural or man-made seaward protection). If the coastal hinterland is low-lying then potentially large-scale effects may occur during extreme events (e.g., East Anglia). Such severe flood events typically occur in combination with erosion when a protective feature is removed or damaged (e.g., as a barrier breach or changes in estuary morphology). Vulnerable habitats include coastal grazing marsh which are dominantly terrestrial/freshwater features and coastal lagoons, both of which support a large proportion of overwintering and migrating birds in key locations.

In the intertidal zone, inundation influences vegetation composition for saltmarsh communities and if the habitat is not able to migrate inland due to sea level rise, most commonly due to coastal defences, then the inundation frequency may cause a transition to mud flat and the distinctive vegetation is lost. In a healthy condition, saltmarsh is a resilient habitat and can survive extreme water levels, protecting inland locations from flooding. Simulation studies have shown that storm surge effects on saltmarsh elevation incur only minor elevational changes (Spencer *et al.*, 2015).

#### 3.18.1.1.4 Species and Habitats

It has not been possible to complement the risk data for designated areas cited above with an updated analysis of priority habitat lost or degraded by coastal erosion or flooding, representing an important evidence gap. We therefore assume the summary findings reported in CCRA2 regarding current habitat loss remain valid. Current trends have been summarised by the Office for National Statistics (2016) based upon the previous JNCC data interpreted by the time-series analysis of Beaumont *et al.* (2010, 2014; Table 3.55). The total extent of the intertidal zone in the UK has therefore decreased due to erosion from sea-level rise and coastal squeeze from hard built structures preventing natural roll back but no overall updated assessment of changes in the intertidal zone has been completed. In 2016, CCRA2 identified ca. 1200 ha of internationally protected intertidal habitat and a further 500 ha of coastal freshwater habitat that will be lost due to coastal squeeze over the next 10 years. The implications for protected species will obviously depend on the type and location of habitat affected.

Condition monitoring of coastal habitat areas also continues to show that much of it is in an unfavourable condition. In addition to protected area monitoring, saltmarsh habitat condition is now being included in Water Framework Directive (WFD) assessment of 'good ecological status'. In England, of the 40 WFD coastal/transitional water bodies assessed in 2016, 1 was of poor status, 24 were in moderate status and 15 were in good status; reduction in habitat extent and over-domination of the existing saltmarsh by one sub-habitat zone (as a consequence of coastal squeeze eroding the lower marsh) being the main issues for not meeting good status. In Wales, using the same criteria, 3 water bodies had moderate status, 7 had good status, and 3 had high status. In

Scotland and Northern Ireland, saltmarsh WFD status has not been completed yet, however in Scotland previous SNH surveys of sites >3 ha (dating to 2010-2012) showed that 67% of all sites and 69% of SSSI sites failed their condition assessment (Haynes, 2016).

**Table 3.55** Current trends in coastal habitat\* loss (ha/yr) (extrapolated from Beaumont *et al.* 2010, 2014)

	Saltmarsh	Sand dunes	Shingle	Machair
England	75.54	21.42	4.02	-
Northern Ireland	0.56	2.5	-	-
Scotland	13.5	72.86	-	23.64
Wales	15.64	9.72	-	-

\*2010 UK habitat areas (ha): saltmarsh 46631; sand dunes 70853; shingle 5852; machair 19698

Coastal habitats are dynamic features. If the ecosystem has retained the natural interaction between biotic and abiotic components, changing patterns of flooding and erosion may therefore be accommodated within a normal sequence of coastal habitat evolution, although obviously there are also limits to this natural resilience (as discussed below).

A further consideration for coastal habitats and species is the additional influence of direct climate effects, notably temperature and precipitation changes. Warm-favouring species of rocky intertidal habitats have continued to expand their range, either north along the west coast, or east along the south coast; examples include the topshell *Phorcus lineatus*, limpet *Patella depressa*, and barnacle *Chthamalus stellatus* (Burden *et al.*, 2020). Regarding precipitation changes, previous evidence reported in CCRA2 identified that dune slacks in England may be drying out due to changes in hydrological conditions. This has been linked with a reported 30% reduction in dune-slack extent in the largest protected sites between 1990 and 2012, and the remaining dune slacks show shifts from wetter to drier plant communities; however, further survey is now required to reconfirm these findings, especially in the context of recent increased frequency of wetter summers in many locations. An increase in intense rainfall events may also have negative impacts on seabirds that nest in burrows due to flooding of these sites, as occasionally occurs at present.

As with terrestrial habitats (Risk N1), some coastal habitats have considerable natural inertia meaning that, in the absence of disturbance, existing vegetation (notably dominant species) can have a strong intrinsic resistance to displacement. For example, a resurvey of dune vegetation from 89 sites in Scotland based upon a ca.34-year time lag found very limited establishment of new species from more southerly locations as may have been expected with climate warming (Pakeman *et al.*, 2015). In addition to natural resistance to change, this may be attributed to limits on dispersal to geographically isolated sites, or to management interventions that favour current species, or potentially to other climate-related factors that may predominate over temperature influence.

Regular species monitoring data is strongest for birds. Breeding seabird status has not achieved 'Good Environmental Status' (GES) as defined by the UK Marine Strategy (Defra, 2019c). Surveys have indicated over a third of UK seabird species showed declines of 20% or more in breeding abundance since the 1990s, with the decline apparently increasing in the last decade (Defra, 2020b; Mitchell *et al.*, 2020). The UK breeding seabird index (based upon the populations of 13 species) in 2018 was 28% lower than at its starting date in 1986, and only slightly above its lowest level ever recorded (-29% in 2013) (Defra, 2020b). This indicator has shown a sustained decline since the mid-2000s but in the shorter term, 5 of the index species have increased strongly (+30-40%) between 2012 and 2017 (razorbill, Arctic tern, common tern, great black-backed gull and great cormorant). The UK seabird index and its overall trends continues to exhibit a different pattern to the England index which is at least partially related to different species compositions. Some species breed only in Scotland whereas others are more widespread but with the bulk of their populations in the northern UK, meaning data is insufficient for an England-only trend. Interactions between seabirds and the wider marine environment, including the indirect effects of changes in prey availability (notably declines in sandeels) are discussed in Risk N14.

In summary, different species have varying climate sensitivities, both direct and indirect, and this also varies with location which also implicates the interaction of climate with other varying stresses (e.g., fishing pressures; pollution). Shorter-term climate variability and extreme weather events have a clear direct influence such as through severe wreck losses for some species (e.g., puffin), or from flooded burrows (Moffat *et al.*, 2020). However, scientific consensus also suggests an important indirect link to climate change through the availability of food, notably small fish such as sandeels (Howells *et al.*, 2017, 2018; Wanless *et al.*, 2018; Mitchell *et al.*, 2020). This is supported by evidence that surface feeders seem more affected than those feeding in deeper water and that there are distinctive spatial variations for some species declines (e.g., kittiwakes), which have been attributed to varying temperature impacts on sandeels and their copepod prey (Carroll *et al.*, 2017). These shifts in both predators and prey may also be contributing to a 'trophic mismatch' whereby seabirds have not kept pace with a temperature-related transition to an earlier annual sequence of sandeel life cycle events, notably in the North Sea (Defra, 2019c; Mitchell *et al.*, 2020).

The general distribution for coastal winter waterbirds shows ongoing north-easterly shifts. Waders show a positive correlation between winter temperature and abundance, and this is assumed to be due to increased food availability and reduced energy demands in warmer conditions (Pearce-Higgins and Green, 2014). Warmer winters are also associated with advanced timing for spring departure from coastal overwintering habitats to breeding grounds. Nevertheless, populations patterns are also complex, with evidence also suggesting that some waders are declining in numbers, and that this may be related to warmer, drier summers in their breeding grounds or disturbance from agricultural land-use changes (e.g., drainage of wetland habitats) (Pearce-Higgins *et al.*, 2017).

### 3.18.1.2 Future risk (N17)

#### 3.18.1.2.1 Sea-level rise and other Climate-related factors

Sea-level rise is the key determinant of changing risk magnitude in the future. When evaluating evidence for CCRA3 compared to CCRA2, it is therefore especially noteworthy that the median and upper range for UK sea-level rise projections have now been revised upwards in UKCP18 (see Chapter 1: Slingo, 2021) as further supported by recent sensitivity analysis based upon extrapolation of observed changes relative to the degree of radiative forcing and global warming (Grinsted and Hesselbjerg, 2021). This implies an increased future risk from coastal flooding and erosion hazards.

Changes in wave and tide regime remain rather uncertain but a precautionary risk management approach would recognise the potential for these regimes to also be further modified by climate change. As discussed in Chapter 1 (Slingo, 2021), some future projections for North Atlantic storms over the 21st century show an overall reduced frequency, and some indicate a poleward shift in winter storm tracks. Chapter 1 (Slingo, 2021) also highlights new climate model evidence suggesting increased winter cyclonic activity for the UK. Similar uncertainty pertains for the wave regime, especially as this is strongly influenced by frequency of large-scale atmospheric circulation patterns that are challenging to accurately simulate in climate models. Recent projections suggest a reduction in mean wave height, but an increase in the most severe wave heights, notably to the SW of the UK (e.g., Aarnes *et al.*, 2017). Analysis using an ensemble of wave models with the RCP4.5 and RCP8.5 scenarios projects the most extreme waves (100-year significant wave height) to increase by up to 5% in the SW and NW of the UK with but could decrease elsewhere (Meucci *et al.*, 2020). The current position is therefore that we cannot exclude an increase in wave-driven erosion as a plausible scenario in vulnerable locations, including inter-related effects on flooding, as notably evidenced by impacts during the recent winter of 2013/14.

Changes in local and regional tidal dynamics are known to have occurred in the past due to non-astronomical factors, such as changes in 3D coastal morphology and interaction with river flows, and therefore may be anticipated to occur in future, but the complex interactions with global sea-level rise and local meteorological factors (e.g., radiational forcing of water) make future projections rather difficult (Haigh *et al.*, 2019). Furthermore, indirect effects of climate change, such as through modified river discharges and morphological changes from managed realignment, may also be expected to have an influence. In addition, and more predictably, astronomical factors are known to influence decadal variations in local water levels, notably the amplification of the 18.6-year lunar cycle in estuaries (Wang and Townend, 2012), which will also therefore have an influence on extreme water levels, and associated flood and erosion risk, in future.

Many estuaries are important foci for nature conservation interests; however, estuaries are complex features and their response will also depend on any changes in fluvial inputs, together with surface water runoff and groundwater, in addition to the marine influence (Robins *et al.*, 2015). In general, the interaction of estuaries with the open coast will depend on the tidal asymmetry of the inlet: when the inlet is ebb-dominant (flood-dominant), sea-level rise may cause an export (import) of sediment, that acts to counter (accentuate) retreat of the adjacent coast. Larger estuaries may be especially susceptible to erosion due to the increased tidal prism, although estuary widening can partly mitigate adverse effects if an expanded intertidal area is available to provide sediment for

adaptation; by contrast, a slightly reduced tidal amplification may be expected in small estuaries (Leuven *et al.*, 2019).

Risks from both erosion and flooding will also be greater for locations that are more exposed or have intrinsic susceptibility to extreme storms. As discussed in CCRA2, more episodes of extreme storminess such as occurred during winter 2013/14 would have major implications for coastal erosion, as these stormy periods incur an extended recovery time which may potentially become greater than the interval between major storm episodes, and hence recovery does not occur. For example, a study of erosion rates at two vulnerable cliffs in Cornwall during winter 2013–2014 recorded erosion rates 3-5 times larger than the long-term average since 1948 (Earlie *et al.*, 2018).

#### 3.18.1.2.2 Coastal Erosion and Accretion

The expectation for the rate and extent of coastal erosion in the UK, based on our existing knowledge of the underlying processes, is that both will further increase. This increase is a consequence of both further relative sea-level rise and the legacy of past management decisions including from reduced nearshore sediment supply that would otherwise be available to buffer sea-level rise and facilitate habitat resilience. As a result, it is highly likely many areas of presently stable or accreting coasts will enter an erosional phase, whilst erosion rates will increase on existing eroding coastlines (Masselink *et al.*, 2020). For those areas of the coast that are protected by hard defences, the position of the coastline will become increasingly divergent from a natural dynamic equilibrium transition that would occur without defences. Our assessment of the implications of this divergence for a specific area of coastline are that removal of coastal protection would be very likely to be followed by accelerated erosion as the coastal processes adjust towards some form of equilibrium; this has been evidenced by high erosion rates following removal of defences at locations such as Happisburgh (Norfolk) (average annual erosion rates increased by 7 to 17 times: Walkden *et al.*, 2016). Alternatively, that location becomes increasingly dependent on man-made coastal protection for risk management but with consequent implications for adjacent sections of coast (e.g., through disruption to longshore sediment transport).

Indicative projections of coastal erosion extending to 2050 and 2100 have been derived based upon extrapolation of current rates for England and Scotland, providing general inferences of areas at risk, although currently no further information is available to update CCRA2 based upon implications for priority habitats. Hence, in England analysis for the NCERM (Rogers *et al.*, 2008) of the area of SSSI 'at risk' from erosion has produced for 2050 a central estimate (50% likelihood) of 1600 ha and an upper estimate (5% likelihood) of 2000 ha. Comparative reference values for 2100 were 2800 ha (central estimate; or 3100 ha including complex cliffs) and 3500 ha (upper estimate; or 4400 ha including complex cliffs). These projections are indicative of expected changes in risk but do not yet incorporate a recognition that SSSI status is often related to the dynamic evolution of a habitat or underlying landform, rather than being a static feature, and erosion of sediment from one location may actively support habitat development at another.

In Scotland, the Dynamic Coast project has not yet projected future coastal erosion risk due to changing climate drivers, but implications have been derived by assuming a continuation of the same recent historic rates since the 1970s (Fitton *et al.*, 2016; Hansom *et al.*, 2017). This would imply that by 2050, ca. 350 ha of the SEPA indicative coastal floodplain (i.e., the notional area of risk

exposure for a 1-in-200-year flood event) would be affected. Within this zone it can be assumed that low-lying coastal dunes, machair and salt marshes, together with associated terrestrial or freshwater habitats, would be mostly at higher risk, especially if erosion extends above the MHWS level as occurs during severe storm events. In addition to erosion, the coincidence of erosion with flood risk would be likely to induce a further change in flood frequency and extent of inundation, although at some sites, localised accretion may provide some protection. In terms of designated protected areas, these forward projections indicate that 88 ha of NNR, 223 ha of SAC, 266 ha of SPA, and 360 ha of SSSI would be notionally at risk of expected erosion, depending on the rationale for designation (in some cases erosion may have beneficial outcomes, or be consistent with dynamic geomorphic evolution of habitats balancing erosion and accretion; also noting that some locations have multiple designations). These estimates are indicative, and likely to be further refined based on use of future climate change scenarios and analysis that accounts for the 3D geomorphology of dynamic coastal habitats rather than just the assumed changes in MHWS based on a simple planform assessment. More detailed site assessments are also likely to refine these estimates, as erosion (and potentially accretion) at each site involves the interaction of natural processes with the additional effects of changing sea levels, in addition to other possible factors (e.g., tidal dynamics, wave regime), and human interventions on the coastal zone.

#### 3.18.1.2.3 Coastal Flooding

Indicative assessments of the risk of coastal flooding for designated nature conservation sites have been provided by the recent CCC Floods Study (Sayers et al., 2020; Table 3.56), based upon central estimates for the scenarios of 2°C and 4°C global warming in 2100 as related to sea level rise (wave and tidal regime and coastal/fluvial tidal flooding combinations were assumed to remain as at present). These also show a significantly increased flood risk for the future, except for Scotland, and especially for England. However, some caution is required in interpretation as the methodology was not designed to account for the dynamics of the natural environment and again, as above, the actual implications will depend on the rationale for site designation (some species and habitats being more vulnerable to saltwater flooding than others).

**Table 3.56.** Increase in designated areas at significant risk of coastal flooding (frequency of 1 in 75 year or greater) for England, Scotland, Wales, and Northern Ireland, for the 2050s and 2080s on pathways to 2°C and 4°C global warming by 2100 with low population, from Sayers *et al.* (2020). NB. Risk is assessed to areas to landward of coastal defences but does not include changes in inundation frequency and associated risk for habitats on seaward side.

ENGLAND						
Assets at significant risk	Baseline (Ha)	2050s 2°C	2080s 2°C	2050s 4°C	2080s 4°C	
Most Important habitats exposed to frequent flooding	48,434	57%	64%	65%	69%	
Ramsar area in probability bands - Significant	18,649	49%	55%	56%	58%	
SAC area in probability bands - Significant	11,647	68%	76%	79%	85%	
SPA area in probability bands - Significant	18,139	59%	65%	66%	69%	
NORTHERN IRELAND						
Assets at significant risk	Baseline (Ha)	2050s 2°C	2080s 2°C	2050s 4°C	2080s 4°C

#### 3.18.1.2.4 Species and Habitats

In response to ongoing sea-level rise, the natural response of coastal habitats and landforms would be to roll-over and migrate landwards, where topography allows this (i.e., without steeply-rising ground to impede this), meaning that habitats associated with barrier coastlines and estuaries would be maintained in their relative shoreline position. However, this geomorphic evolution will be strongly influenced by other local factors including both concurrent climate-driven processes (waves, tides) and past/present coastal management. Longshore factors will also continue to be a key influence, especially as they are a dominant control on many areas of the UK coastline, hence erosion and accretion will likely occur at different rates and locations alongshore in addition to shoreward profiles, especially where hard defences interrupt the natural response in either direction.

Existing trends for loss of intertidal area are therefore expected to continue, dependent on sea level rise scenario and any change in management regime, and potentially any additional effects from wave and tidal dynamics. For saltmarshes, Horton *et al.* (2018) showed a greater than 80% probability of retreat in extent for the whole of Great Britain by 2100 under a high climate change scenario (RCP8.5) by 2100; for higher risk areas of southern and eastern England, an 80% probability of marsh retreat would occur by 2040. This can be compared with a low climate change scenario (RCP 2.6) where there is a >20% probability of an expansion or of relatively stable outcomes for saltmarsh over the next 200 years for Scotland and NW England but for which there still remains a >80% probability of marsh retreat beyond 2100 for southern and eastern England.

A key influence on the future resilience of habitats will be sediment supply, notably for saltmarsh and mudflat, dune systems, and shingle features, together with the role of other climate variables. With increased sediment supply, future projections for the loss of intertidal area referred to above, may be too pessimistic as active saltmarsh habitats can accrete sediment in-situ, even potentially for considerably higher rates of sea-level rise than at present (Ladd *et al.*, 2019). However, for many areas of the UK coastline, the existence of coastal defences means that intertidal zones are usually in a state of sediment depletion, which imposes constraints on their natural adaptability even with present rates of sea-level rise. Habitat composition is also likely to change: for example, warmer temperatures could favour the existing invasive *Spartina anglica*, causing it to replace native cordgrass, and potentially reducing soil stability which then further increases erosion risk (Ford *et al.*, 2016).

For England, the NCERM (Rogers *et al.*, 2008) has estimated that in the near-term (mid-2020s), some 500 ha of freshwater habitat in the coastal zone will be lost due to coastal squeeze. It has also been estimated that an average of around 4-6% priority freshwater habitats in the coastal floodplain could be lost per year due to saltwater inundation, most of this being in designated areas. However, this assessment does not include episodic inundation caused by extreme storm surges. Some vulnerable habitats such as freshwater grazing marsh are very likely to become at greater risk from increased frequency of coastal flooding either due to overtopping of natural or artificial seaward defences, or due to a major breach of these defences during an extreme event. Whilst this may eventually facilitate a transition to new intertidal habitat (saltmarsh or mudflat), loss of the freshwater grazing marsh may be significant for species that depend on it (e.g., waterbirds, invertebrates, and some

plants), and even if new grazing marsh is created elsewhere there is no guarantee that these species will be able to colonise it (e.g., due to different habitat conditions or constraints on species dispersion).

In addition to constraints related to sediment supply, shingle has rapid drainage and therefore an increased frequency of extended dry periods would be likely to modify vegetation and soil structure through changes to groundwater levels, also increasing vulnerability to further disturbance because recolonization rates are therefore likely to be slower. In some locations, increased disturbance and warmer temperatures may favour invasive species (e.g., Hottentot fig *Carpobrotus edulis*, which is frost-sensitive but already extensive in southern England and has also spread to Wales, Northern Ireland and even recorded by the Biological Records Centre at locations in western and northern Scotland: Burden *et al.*, 2020).

Sea-level rise will also have an important influence on low-lying coasts by modifying groundwater levels and potentially the frequency and extent of waterlogging for some priority habitats. Changing groundwater levels will modify open-water areas, which are important for wintering birds, and may cause substantive losses to ephemeral areas such as dune slacks that are important habitats for rare taxa, such as some amphibians (Rhymes *et al.*, 2016). Similarly, for machair habitats, future biodiversity will strongly depend on water management and continued effective drainage of excess precipitation (much of the machair is artificially drained) and prevention of marine incursion through breaching of dune systems or wave overtopping, of which the risks will especially increase due to ongoing sea level rise (Angus, 2018; Angus and Hansom, 2021).

Based upon a continuation of current climate pressures, some seabirds may become extinct in the UK by 2100 (e.g., Leach's storm petrel; great skua; Arctic skua) whilst other species are likely to have reduced ranges (e.g., black-legged kittiwake; Arctic tern; auks) (Burden *et al.*, 2020). Modelling work based upon the indicator species used for the UK breeding seabird index (see 'Current risk' above) has inferred that even the index species currently showing increased populations (excepting common tern) are at significant risk of future declines due to climate change effects (Davies *et al.*, 2020).

Six of the priority non-breeding UK waterbird species, have been identified as at high risk of UK range loss, with arctic-subarctic breeding species especially vulnerable to major changes in their breeding grounds; a further 14 species have been identified at moderate risk, whilst 20 species are projected to benefit through range expansion (Mendez *et al.*, 2018). These risks and opportunities may be expected to lead to considerable species turnover at individual protected areas: the same study found only 10 of 57 SPAs were projected to lose all qualifying species by 2050, and 11 SPAs by 2080. Projected increases in abundance could result in six to seven new designated sites supporting internationally important numbers, although this will require continued availability of intertidal and coastal grazing marsh habitats despite sea level rise. As noted above, there are important uncertainties in the projected future responses of both estuaries and the intertidal zone, due to the interaction of multiple morphodynamic and hydrodynamic factors with sea-level rise. These could have additional implications for species such as waterbirds that rely on both the extent and quality of habitat for food and shelter. As discussed in section 3.18.2, a key risk management issue for

adaptation will be whether habitat loss due to sea-level rise is compensated by habitat creation shorewards, either naturally or through additional managed interventions.

#### 3.18.1.3 Lock-in (N17)

The main lock-in effect is that most sections of the coast are continuing with 'hold the line' (HTL) policies, either as defined by the Shoreline Management Plan (SMP) or in practice. In the latter case, as discussed further below in terms of adaptation (section 3.18.2), the practical issues occur due to local resistance to a shift away from HTL. The end-result is to create an unsustainable long-term legacy for the coastal zone as the shoreline becomes further out of its dynamic equilibrium position as sea-level rise increases. This means that when a shift in approach is eventually made towards a more sustainable long-term policy (some SMPs indicate a shift away from HTL in a future management epoch), there can be difficulties in establishing a non-abrupt transition away from the current position, meaning that local erosion rates can increase substantially. It is our assessment that limited short-term protection from erosion and flooding risk is therefore in many locations being achieved at the expense of a notable increase in long-term risk, unless coastal protection schemes are substantially upgraded, which for many locations would be considered too costly unless to protect major settlements (Chapter 5: Kovats and Brisley, 2021) or infrastructure (Chapter 4: Jaroszweski, 2021).

It is also worth noting that a HTL policy may vary according to region and therefore current SMPs sometimes contain inconsistencies. For example, a shingle barrier may be defined as a HTL feature or to have no-active intervention. In the case of HTL, this may involve engineering intervention through re-profiling of the shingle barrier to maintain it in its current planform position, but with the risk that, by not allowing natural rollover, it is increasingly exposed to the possibility of a catastrophic breach as the lower foreshore continues to adjust to changing hydrodynamic drivers.

In consequence, areas with HTL policies will need to regularly re-evaluate their full implications in both short-term and long-term, including recognition that HTL coastal segments may affect other adjacent areas through modified sediment supply. With regard to coastal habitats, this means that in some locations there are difficult decisions to be made between the conservation of intertidal habitats through managed realignment of coastal defences or conservation of inland habitats (e.g., freshwater grazing marsh) that rely on defences to remain in situ and would otherwise require compensatory habitat elsewhere. However, compensatory habitat for displaced freshwater or terrestrial habitats may then require re-allocation of farmland or other land uses, necessitating extensive consultation and negotiation. Most notably for coastal biodiversity, realisation of opportunities requires a managed transition away from maintaining the status quo, providing accommodation space for habitat evolution. Wider benefits of coastal habitats through alleviation of flooding and erosion hazards also need to be more explicitly incorporated into management decisions.

#### 3.18.1.4 Thresholds (N17)

The rate of sea-level rise is a key threshold for the erosion rate and flood risk in combination with available sediment supply. When the rate of sea-level rise exceeds the buffering capacity of habitats

to remain in situ (which is also sustained by sediment supply) then a step change to more rapid erosion can occur. The saltmarsh analysis by Horton *et al.* (2018) cited above used Holocene sedimentary records to infer that marshes become nine times more likely to retreat than expand when relative sea-level rise rates are  $\geq 7.1$  mm/yr. Threshold effects also occur on coasts with hard defences as sea-level rise increases the hydrodynamic loading on the defences and on habitats on the seaward side, therefore increasing the detrimental effects of coastal squeeze. If the defences are removed or breached, then a rapid step change of the shoreline can also occur to a new dynamic equilibrium position, which may incur rapid habitat change or loss for areas formerly landward of defences. Threshold effects can also occur with changes in wave energy regime (wave height, direction etc.) and during extreme events with abnormal high-water levels.

#### 3.18.1.5 Cross-cutting risks and inter-dependencies (N17)

There are many cross-cutting interactions involved that together require an integrated approach to coastal management. Erosion and flooding are inter-related through coastal dynamics and isolated management responses to one type of hazard can accentuate the other elsewhere on the coast or exacerbate the risk in the longer term (Pollard *et al.*, 2019). Coastal habitats have an important hazard alleviation role that when degraded can increase negative outcomes for infrastructure (Chapter 4, Risk I3: Jaroszweski, Wood and Chapman, 2021), the built environment (Chapter 5, Risk H4: Kovats and Brisley, 2021), agricultural land (Risk N6), and associated businesses (Chapter 6, Risk B1, B2: Surminski, 2021). Coastal habitats and species also provide important cultural benefits to people including through amenity value and landscape character (Risk N18) whilst also providing inshore fisheries and carbon storage/sequestration benefits (Risk N5). Furthermore, it is important to recognise that coastal habitats also contain many cultural and historic assets (e.g., related to maritime activity and coastal defence) and decisions on future management options also need to take account of these (see Chapter 5: Kovats and Brisley, 2021). For example, on the Welsh coastline over 100,000 historic assets of all periods and types have been identified, and Cadw have identified 16% of these to be at risk from sea level rise. In many instances, coastal cultural heritage cannot be moved and if physical loss is inevitable there is a need for that heritage to be continued through other forms (e.g., full documentation, or the use of narrative storytelling to capture the cultural and landscape/seascape context). In a dynamic coastal setting, challenges in integrating policies for conservation of both the natural environment and cultural heritage therefore need to be better recognised and addressed more strategically in coastal planning. There is also increased interest in using enhanced public engagement and citizen science in understanding the linkages between coastal heritage and natural processes in the context of climate change (e.g., Scotland's Coastal Heritage at Risk Project: Dawson *et al.*, 2020).

A further complicating factor in some locations is the interaction with invasive species that can modify the natural succession of coastal ecosystems. A prominent example is the presence of the invasive hybrid cord grass *Spartina anglica*, notably in southern England (Biological Records Centre, 2021). This can increase local sedimentation rates and colonisation of mudflats to saltmarsh, whilst also negatively impacting pioneer communities of saltmarsh, especially on *Salicornia* communities. However, the long-term outcome of these interactions in a changing climate remain uncertain.

Finally, specifically in relation to coastal ecosystem services, there are likely to be important implications for management of this risk in relation to societal inequalities (see 'section 3.18.1.7 below), notably for vulnerable coastal communities that are either directly or indirectly reliant on the continued availability of natural alleviation of coastal hazards (see Chapter 5: Kovats and Brisley, 2021).

#### 3.18.1.6 Implications of Net Zero (N17)

There are potential implications through increased development of coastal renewable energy sources, which may have both positive and negative impacts on coastal habitats and species. Also, coastal habitats (notably saltmarsh) can be important carbon sinks: for further discussion of the important opportunities for 'Blue Carbon' through habitat creation/restoration, as would occur with a larger-scale shift towards managed coastal realignment, see Risk N5 (section 3.7). Coastal habitats are at present not included in the UK GHG emissions inventory, ostensibly due to the large uncertainties involved with regard to emissions and sequestration values, but this should not be a significant barrier for a Tier 1 type assessment (including sensitivity testing of different emission factors), especially by comparison with the similar uncertainties in the LULUCF sector (as reported elsewhere in this document, including for peatlands which are now planned to be included). The key issue here is the significant contribution that coastal habitats could make to reducing atmospheric GHG concentrations, rather than assumed impediments in accounting procedures.

#### 3.18.1.7 Inequalities (N17)

Implications for loss of ecosystem services, notably if continued habitat loss results in increased risk from coastal flooding and erosion, are also likely to have implications for vulnerable communities in affected areas (see Chapter 5: Kovats and Brisley, 2021) that currently benefit from natural coastal protection (e.g., sand dunes, shingle bars, intertidal zone). This could therefore exacerbate social inequalities, as for example in locations where SMPs and government cost-benefit calculations imply no further intervention will occur and structural defences removed or allowed to degrade, and therefore it can be identified that there is an assumed dependence on natural coastal protection.

#### 3.18.1.8 Magnitude scores (N17)

Magnitude categories in Table 3.57 are based on expert judgement and assessed in terms of existing or expected impacts on biodiversity (including viable metapopulation sizes), ecosystem functioning, and ecosystem services (excepting carbon storage – Risk N5). This approach is also followed because indicators based upon species numbers or habitat area are only crudely indicative of systemic risks. Risk magnitude is assessed as increasing from medium at present to high in the future (all climate projections) due to the strong relationship with sea-level rise and other climate factors and the current constraints on natural adaptive capacity. Confidence in this assessment is medium for the present but reduces to low-medium in future (only low confidence for Northern Ireland for both present and future). This is because evidence for changes in priority species and habitats is limited (more detailed evidence is often available only for certain locations), and although there is good general information on the present-day extent of coastal impacts, the combination of multiple factors in future (including socioeconomic factors) means the full risk magnitude is difficult to project forwards.

**Table 3.57** Magnitude score for risks and opportunities to coastal species and habitats due to coastal flooding, erosion, and climate factors

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium (Medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)
<b>Northern Ireland</b>	Medium (Low confidence)	High (low confidence)	High (low confidence)	High (Low confidence)	High (Low confidence)
<b>Scotland</b>	Medium (Medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)
<b>Wales</b>	Medium (Medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)	High (low-medium confidence)

### 3.18.2 Extent to which the current adaptation will manage the risk (N17)

#### 3.18.2.1 Effects of current adaptation policy and commitments on current and future risks (N17)

##### 3.18.2.1.1 Flood and coastal erosion risk management policies

##### 3.18.2.1.1.1 UK-wide responsibilities and strategies

Across the UK, responsibilities for flood and erosion risk management are varied and operate at multiple scales (see below). This has increased relevance in terms of both the delivery of strategic responses to climate change and the role of the natural environment in those strategic responses through: (i) protection for priority species and habitats; (ii) protection for designated nature conservation areas; (iii) multiple societal benefits provided by coastal ecosystems and their interaction with people, settlements, infrastructure, and businesses.

Across all the UK, under the implementation of the Floods Directive (UK Flood Risk Regulations (2009) and devolved equivalents), Flood Risk Management Plans (FRMPs) and Flood Risk

Management Strategies (developed to co-ordinate local plans in Scotland) have been produced for coastal districts.

In each case, national strategic guidance for coastal management aims to ensure decisions are sustainable. The key implementation mechanism at local and regional level is usually through Shoreline Management Plans (SMPs), which are based on natural boundaries (littoral sediment cells) rather than administrative units. All of England and Wales is covered by SMPs, but only part of Scotland (ca.8% of the coastline), and none of Northern Ireland has an SMP or equivalent plan. Where an SMP is available, it is intended that it contributes to an area's overall flood risk management plan including to provide a joined-up approach across risk management authorities. By identifying recommendations required to achieve a sustainable coast, SMPs also have a key role in conserving habitats and species.

#### 3.18.2.1.1.2 Shoreline Management Plans (SMPs)

The SMP process in combination with active coastal partnerships has been shown to facilitate a constructive pathway towards sustainable and integrated coastal zone management (e.g., Ballinger *et al.*, 2020), although the quality of plans is variable, with not all following and implementing the holistic long-term vision established by the earliest plans in the current implementation cycle (2<sup>nd</sup> generation in England and Wales). SMPs define coastal management decisions in the short-term (0–20 years), medium-term (20–50 years) and long-term (50–100 years) although these epochs are defined for England and Wales based on the start of the current (i.e., second-round) implementation cycle (2009–11), rather than being incrementally updated; therefore, the current short-term epoch will in end in a few years. SMPs remain advisory rather than statutory instruments, which can mean that in practice the recommendations are not necessarily funded or implemented. Currently, in England and Wales a SMP Refresh is underway to incorporate new legislation, knowledge and information into existing plans, including climate change projections, and to provide supplementary guidance for helping to manage the implementation of SMP policies, including a consistent template for SMP action plans (further details on SMPs are provided in Chapter 5: Kovats and Brisley, 2021). This SMP Refresh is therefore anticipated to initiate a new planned implementation cycle, although details of how this will actually change plan outcomes (including for both climate change responses and protecting habitats and species) is yet to become available or independently assessed. Therefore, at present, we do not have independent evidence on how the SMP Refresh will change existing SMP plans or their implementation in practice.

A major challenge for adaptation is that plans, as outlined by SMPs based upon analysis of local evidence, are not being fully delivered (House of Commons, Environment, Food and Rural Affairs Committee, 2019). Analysis by the CCC (2018a) for England has indicated that 111 km of coastline had been realigned by 2016, but that the average realignment rate of 6 km/yr for 2000–2016 falls well short of aspirations in SMPs to realign 550 km by 2030 (ca. 30 km/yr). Similarly, habitat creation schemes were found to total 2220 ha by 2016 (a rate of 130 ha/yr) which also falls short of ambitions in the SMPs to create 7500 ha by 2030 (ca. 400 ha/yr). Equivalent analysis for Wales, Scotland or Northern Ireland is not available. Further discussion of progress regarding current habitat compensation programmes is provided below.

In some locations there is a notable mismatch between local plans in coastal areas and the relevant SMP for that area. CCC (2018a) analysis found that up to one third of coastal local plans in England show no evidence of using the SMPs as their required evidence base; for the rest of the UK no equivalent review has taken place therefore the position there remains unclear. It has also been noted that the requirement for the SMPs to underpin coastal development strategies in England has been removed from the 2018 revision of the National Planning Policy Framework (NPPF) and instead moved into the Planning Practice Guidance (PPG), which may be considered to give it lesser importance, although PPG can have utility as a working policy document to include best practice. Furthermore, the CCC (2018a) also found that local plans in England only extended to 2036 at best, therefore not encompassing the full long-term recommendations of SMPs. The NPPF (England) identifies that areas "likely to be affected by physical change to the coast" should be demarcated as Coastal Change Management Areas (CCMAs) and the local planning authority should then ensure that "inappropriate development" is avoided. Physical change in this context refers to coastal erosion rather than flooding. However, in practice CCMAs are not defined for areas where a HTL policy is in place, despite the likelihood that this policy may be (or become) unsustainable due to climate change. Hence, this mechanism to assess and discourage inappropriate development is not fully activated, and problems from policy lock-in may therefore be perpetuated.

Discrete coastal segments are distinguished within SMPs as local management units. However, the basis for these has been criticised for being defined primarily based upon the hazards currently experienced, or the urban or rural characteristics of the hinterland, neglecting other considerations that are important for risk assessment including broader social, economic and environmental vulnerability contexts, or the compound nature of the hazard in many locations (Townend et al, 2021).

A further challenge for SMPs, and coastal zone management in general, is addressing more recent projections for high rates and magnitudes of sea-level rise (Chapter 1: Slingo, 2021). Implementation of current plans is usually based upon a single future projection that has been carried forward from past assessments and also contain notable inconsistencies. Analysis in England and Wales has shown that the different planning processes and timetables involved for SMPs and CFMPs (Catchment Flood Management Plans, which are developed for tidal rivers) has led to inconsistencies regarding use of future sea level rise projections provided through government guidance (Kuklicke and Demeritt, 2016).

A more robust approach to adaptation planning would include a range of range of future projections, including the possibility of significantly higher upper-end estimates (>10 mm/yr) that may make some current preferred policies for specific sections of coast unviable with regard to the stated outcomes. As noted in the CCRA2 Evidence Report, a notable exception here is the Thames Estuary 2100 project in which multiple adaptation pathways were scoped consistent with a range of sea-level rise projections, but since CCRA2 this exemplar has not been followed up through a wider range of similar example plans for the UK coastline to our knowledge.

Current policy developments for each nation can be summarised as follows:

### 3.18.2.1.1.3 England

Defra has overall national responsibility for policy on flood and coastal erosion risk management in England, with the Environment Agency having a strategic overview to ensure that decisions by local authorities and others on the coast are made in a joined-up manner, whilst also being the lead organisation for main rivers and tidal flooding. Erosion management is the responsibility of coastal local authorities. The Environment Agency works together with Coastal Protection authorities to develop Shoreline Management Plans which aim to identify the most sustainable approach to managing coastal flood and coastal erosion risks.

The Government has now proceeded to develop a new policy framework and strategy for the coming decades, the objectives for which have been set out in the new flood and coastal erosion risk management policy statement and associated National Flood and Coastal Erosion Management Strategy (EA, 2020; HM Government, 2020). The Strategy and Statement recognise the key role of natural processes in risk reduction for people and places, together with the need to develop more flexible approaches (adaptation pathways) to correct current problems with lock-in (as discussed above in 3.18.1.3, past decisions to defend a section of coast have continued to have a strong influence on current decisions, despite increased recognition that climate change is modifying coastal processes). The Strategy and Policy Statement include a commitment to 'double the number of government-funded projects which include nature-based solutions to reduce flood and coastal erosion risk' although as yet no further information on these projects (e.g., scale; coastal locations etc.) is available. Funding (£150 million across 25 local areas) will target projects that demonstrate how practical innovative actions can work to improve resilience to flooding and coastal erosion. It is proposed that the FCERM strategy will provide annual progress reporting on a series of measures consistent with the Floods & Water Management Act. In addition, it is expected that changes to the formula for allocating funding for flood and coastal defence schemes across England will result in increased payments for flood schemes which also create a range of environmental benefits.

It is also intended that there will be a review of the effectiveness of existing planning policy on Coastal Management Areas and the current mechanisms and legal powers Coastal Protection Authorities can use to manage the coast. National policy for Shoreline Management Plans will also be reviewed to ensure local plans are transparent, continuously review outcomes and enable local authorities to make robust decisions for their areas.

The dominant SMP policy at present is Hold the Line (HTL: covering 52% of the coast) with a much smaller proportion defined for Managed Realignment (MR: 10%), and the remainder being No Active Intervention (NAI: 38%). For future epochs, the overall balance changes, although not greatly, both for 2025-2055 (HTL: 46%, MR:16%, NAI: 38%) and 2055-2105 (HTL: 46%, MR:15%, NAI: 39%). This also disguises considerable regional variation (e.g., much of south-west England is designated as NAI, whereas much of south-east or east England remains HTL). However, as noted above, a SMP Refresh process is now underway to reappraise plans in the light of new evidence and policy objectives, with strategic oversight by the Environment Agency and updated guidance to supplement the previous guidance published in 2006. It is also intended that SMPs become more like 'living documents' that are regularly reviewed and updated than they have been in the past, including with the 5-year cycle for Local Plans. As part of this process, research to better understand and contextualise historic

coastal change is currently underway, including issues associated with 'coastal squeeze' (see 3.18.2.1.2 below).

#### 3.18.2.1.1.4 Northern Ireland

In Northern Ireland, the Rivers Agency operates as a strategic agency of the Department for Infrastructure to address flooding issues. There is no legislation in place to specifically address coastal erosion or assign responsibilities (hence there is no department with lead responsibilities); instead, coastal assets are looked after by the respective government department whose responsibilities most closely coincided with the property or asset at risk from erosion (the 'Bateman formula': 1967). This piecemeal approach has tended to act against a strategic approach to coastal erosion risk management which is exacerbated by rather limited data and knowledge on current risks (Cooper *et al.*, 2016; DAERA, 2019b). Nevertheless, the responsibility for the appropriate management of coastal changes lies principally with DAERA and DfI, with DAERA responsible for nature conservation. A recent baseline study and gap analysis of coastal erosion risk management in the country (DAERA, 2019b) also identified a lack of strategic coastal data and an ineffective current policy and monitoring framework by comparison with other countries. DfI Rivers is currently undertaking a coastal mapping update study and a high-resolution 3D coastal topographic survey (LiDAR and satellite-derived bathymetry) has recently been commissioned, which will both aim to provide an improved monitoring baseline for risk assessment. Similarly, work underway through the UK-wide Coastal Flood Boundary Conditions Update project should provide improved and up-to-date data on extreme still water sea levels for flood risk mapping. The Northern Ireland Marine Plan (2018) includes climate change, coastal processes, land/sea interactions, and cumulative impacts as core components, all of which are highly relevant to the coastal environment, but the Plan is yet to be adopted by government.

There has been no development of SMPs in Northern Ireland (or an equivalent coastal planning mechanism), although there is increasing awareness of the need to approach coastal issues more strategically and to improve data collation (Cooper *et al.*, 2016). Current efforts are therefore focussed on collating baseline data to confirm the scale of the challenge for both flooding and erosion. For example, although current data for recent decades suggests that the acceleration in the rate of relative sea-level rise has been similar (ca. 2.3mm/yr) to the rest of the UK and Ireland after local land movements have been accounted for (see Chapter 1: Slingo, 2021), the quality of data has been questioned due to discrepancies and over-reliance on the tide gauge at Belfast (Murdy *et al.*, 2015). This therefore remains a crucial issue for distinguishing shorter-term periodic variations from the long-term sea level trend, and therefore resulting implications for both current and future coastal change (Orford and Murdy, 2015).

#### 3.18.2.1.1.5 Scotland

The Scottish Government has national responsibility for policy on flood management, with SEPA as strategic flood risk management authority. For coastal protection, Scottish Government has national responsibility whilst local authorities have powers on protecting land from incursion by the sea in their respective areas, although legal responsibility remains with the landowner. Whilst SEPA are not responsible for the management of coastal erosion, consideration has been given to this in FRMS by identifying areas that are likely to be susceptible to erosion, as well as areas where erosion could exacerbate flood risk (although there is scope for further improving flooding/erosion interactions).

Scottish Planning Policy clearly states that: *"...new development requiring new defences against coastal erosion or coastal flooding will not be supported except where there is a clear justification for a departure from the general policy to avoid development in areas at risk. Where appropriate, development plans should identify areas at risk and areas where a managed realignment of the coast would be beneficial."*

The government-funded Natural Flood Risk Management Network aims to share knowledge and best practice on natural flood management. The policy framework is also supporting Dynamic Coast which has conducted a first-phase assessment of coastal erosion risk; its second phase will investigate the resilience of Scotland's natural coastal defences (for example, identifying where low dunes may breach), estimate how future climate change may exacerbate flooding and erosion, and develop risk management, adaptation and resilience plans. This will inform ongoing development of SMPs and Flood Risk Management Strategies, including further scope for nature-based solutions, of which there are presently a range of guiding examples including the recent scheme at West Sands (St. Andrews) in response to the 2010 storm surge, and the community-based investigation of such schemes on the machair coast of Uist (Angus and Hansom, 2021). Guidance has also been produced on the implications of Dynamic Coast for development planning (NatureScot, 2020). However, there remain many important evidence gaps and, although monitoring data are available for some locations, it is often rather lacking at national scale, notwithstanding the complexity of Scotland's complex mainland and island coastline. The next phase of Dynamic Coast research will therefore be strongly reliant on improved data acquisition, including to develop robust future erosion projections consistent with the full range of climate change projections for relative sea level rise and other erosion-related parameters (e.g., wave regime). In this regard, it can be noted that adaptation policy could be further enhanced by better inclusion of key indicators on coastal change, reflecting not only species and habitat change, but also progress on adaptation responses, such as through realignment schemes, as supported by improved monitoring data.

#### 3.18.2.1.1.6 Wales

In Wales, responsibilities for flood and coastal erosion risk management are strategically implemented by Natural Resources Wales (NRW). The recently published National Strategy for Flood and Coastal Erosion Risk Management (Welsh Government, 2020) provides a 10-year strategy proposing a shift towards more nature-based solutions and for coastal groups to report annual progress on their SMP action plans through the Wales Coastal Group Forum. In the National Strategy, the Welsh Government also commits to develop and communicate a coastal adaptation toolkit to facilitate engagement with communities, recognising challenges now occurring with vulnerable communities (e.g., Fairbourne: see Chapter 5: Kovats and Brisley, 2021). The integrity of protected (or nationally significant) coastal habitats in Wales is managed through the Conservation of Habitats and Species Regulations 2017. Habitat Regulation Assessments were undertaken for the 4 SMPs in Wales (although using different methodologies), which estimated the amount of compensatory habitat that will be needed to implement the various SMP policies over the 100-year period. The methodology is now being refined and made more consistent to establish an agreed target for all SMP policies in Wales, in conjunction with sediment- and erosion-tracking research through the Wales Coastal Monitoring Centre.

#### 3.18.2.1.1.7 Flood Risk Management Benefits

An indicative assessment of the benefits from a continuation of the current level of adaptation for reduced flood risk to designated nature conservation sites shows that significant gains may be achieved for England and Northern Ireland, and to a lesser extent for Wales (Table 3.58) when compared against the reference risk level presented above without further adaptation (Table 3.56). However, the current level of adaptation produces little extra risk reduction for Scotland (partly because this study assessed the reference risk level as relatively low). Specific assumptions about the definition of current adaptation are available in the Sayers *et al.* (2020) report.

**Table 3.58** Change in nature conservation assets at significant risk of coastal flooding (frequency of 1-in-75-year or greater) for the four nations assuming continuation of current adaptation (Sayers *et al.*, 2020). Note that the effectiveness of the adaptation strategies needs to be ascertained by comparing with Table 3.56.

ENGLAND					
Assets at significant risk	Baseline (Ha)	2050s 2°C	2080s 2°C	2050s 4°C	2080s 4°C

### 3.18.2.1.2 Habitat creation schemes

#### 3.18.2.1.2.1 UK-wide

Despite existing challenges, there is an increasing amount of land assigned to managed realignment and habitat creation objectives, primarily in England. The Online Managed Realignment Guide (ABPmer, 2019) listed 51 managed realignment projects in the UK by 2019; in addition to this, 24 regulated tidal exchange projects have been completed delivering a further 300 ha of coastal habitat, as well as 18 restoration projects involving sediment recharge from ports and harbours. Many of these are small-scale initiatives, but size has been increasing during recent years. Most of the habitat created has been saltmarsh and mudflat in the intertidal zone. For saltmarsh, a total area of 2647 ha has been created from 1991 to 2017 (ABPmer, 2019). The remainder of new habitat consists largely of saline lagoons and transitional grasslands and associated terrestrial habitats. Habitat compensation programmes aim to create new habitat in alternative locations as redress for the habitat lost by man-made coastal defences (including from coastal squeeze) or other built interventions, implementing an obligation under the Habitats Directive to both maintain protected site habitat extents and to ensure the continued coherence of the habitat network. This obligation is especially relevant for SMPs that have led to implementation of HTL policies which are expected to be associated with habitat loss (notably due to coastal squeeze). This occurs when an evidence-based options appraisal indicates the alternative options to HTL are less tenable: in these cases, the decision to commit to habitat loss needs to be formally justified following an Imperative Reasons of Overriding Public Interest (IROPI) test. Habitat creation targets are therefore developed to offset the existing or expected habitat losses. Habitat compensation is intended to be delivered in advance of the loss of existing habitat but has also been retrospectively applied to include past losses in Natura2000 areas back to a notional 1994 baseline. In addition, some areas of intertidal habitat creation involve losses of terrestrial/freshwater habitats inland and this needs to be included in the compensation balance. It is also the stated intention of habitat compensation programmes that habitat targets are kept under regular review to include: potential losses identified through further assessments including new monitoring data; the additional consequences from new plans or projects; and updated projected habitat losses based on new climate change projection. However, at present full details of how this review process will be independently validated and implemented are not available.

More than 95% of the habitat created has been in England, and whilst it could possibly be argued that more opportunities exist in this country, our assessment is that this also reflects a greater emphasis on identifying and realising opportunities despite existing barriers, as also concluded by the Sustainable Shores project (Miles and Richardson, 2018). In addition, England, and to a lesser extent Wales, have moved towards formal accounting and reporting of habitat losses and gains, in the context of coastal defences and coastal squeeze, which also provides a clearer indication of progress in risk management compared to Scotland and Northern Ireland, notwithstanding challenges regarding data quality (which are also increasingly recognised through the formal reporting process). Regarding intertidal habitat, just over 50% was created through habitat compensation schemes, whilst the rest was due to initiatives such as shoreline naturalisation or flood protection benefits.

Although these developments, especially in England, are a positive step, they are dwarfed by the scale of UK historic habitat losses on the coastline before the 1990s (ONS, 2016), including more than 8000 ha of intertidal habitat loss since 1945 (>15% of existing habitat; Miles and Richardson, 2018). This has been especially severe in some locations that are especially vulnerable to increased flooding and erosion risk. Current progress indicators based upon target areas to redress habitat losses from coastal squeeze do not incorporate measures of habitat condition and ecological integrity or functionality, nor the loss of habitat outwith SAC/SPA designated areas (Oaten *et al.*, 2018; Pontee *et al.*, 2021). Hence, it is not clear to what degree the habitat compensation has achieved a 'like for like' replacement, or even whether this is even possible. This refers not only to the biodiversity value of the habitat (the UK Biodiversity Action Plan aims for no net loss and to maintain the quality of the resource in terms of species and diversity), but also the multiple ecosystem functions and services that would be provided by healthy, resilient, and adaptive ecosystems, including also by the natural synergies that occur through the mosaic of inter-connected habitats in the coastal zone, rather than each habitat in isolation. This is more likely to happen with the larger, landscape-scale initiatives.

In addition to their biodiversity importance, evidence also continues to become available that managed realignment and associated intertidal habitat creation can have an important role in reducing flood and erosion hazards although the wide variety of site conditions can make generalisations difficult. Recent analysis by Kiesel *et al.* (2020) has shown that scheme features, including breach design and size of realignment site are crucial in alleviating flood risk: for example, an approximate doubling of site size can increase average wave attenuation rates by about 16 times.

Larger-scale examples of realignment include Alkborough Flats where saltmarsh habitat creation was linked with improved flood storage and flood risk alleviation in the Humber estuary. Medmerry is currently the largest managed realignment project on the open coast undertaken in Europe and has provided flood risk management and 183 ha of intertidal habitat. Another noteworthy example is at Steart (Somerset) in the outer Severn Estuary where setback of the defence line and deliberate breaching of previous flood defences has allowed a diverse range of habitat types to be created (183 ha saltmarsh; 40 ha intertidal mudflat; 69 ha transitional brackish habitat; 79 ha coastal grazing marsh; 32 ha of brackish and saline lagoons; 26 ha of freshwater lagoon). Scotland also now has several examples of managed realignment and SEPA have identified opportunity areas for habitat creation and natural flood management. Although there is uncertainty regarding habitat outcomes, analysis at key sites suggests that removal of embankments will allow the intertidal zone to revert to a more natural process of erosion/accretion which can maintain habitat condition (e.g., Freiston Shore: Ni *et al.*, 2014).

Good practice in developing habitat creation schemes is now being produced, as for example with the Restoring Estuarine and Coastal Habitats (REACH) programme led by the Environment Agency. The compensation rationale extends back to habitat lost since the year 1992 but does not cover the changes that occurred before then, which included the loss of intertidal areas to major land reclamation schemes (often large-scale losses), and which have now significantly modified the natural ecohydrological and geomorphological functioning of the coast.

As identified in the CCRA2 Evidence Report, it is important to recognise that habitat restoration or compensatory habitat may not recreate the same biodiversity, resilience, or ecosystem function and services as in the past. This is especially noteworthy as sea-level rise and other marine influences are being accompanied by other climate-related changes, such as temperature and precipitation. Long-term assessment of ecosystem restoration projects is complex because of ecological processes such as succession, particularly in highly dynamic ecosystems such as estuaries (Boerema *et al.*, 2016).

Current progress in habitat creation and compensation can be summarised as follows:

#### 3.18.2.1.2.2 England

In England, the Habitat Compensation Programme (EA, 2018c), estimated 106 ha freshwater grazing marsh, 1021 ha saltmarsh/mudflat and a further 274 ha of other habitats (mainly reedbeds, but which also includes some saltwater habitats) would be lost between the SMP initiation phase (ca.2010) and end of 'epoch 1' (ca.2025) due to coastal protection schemes. These losses have been offset by creating new habitat compensation areas which are reported to be delivering or already delivered a greater area than that projected to be lost in this epoch (EA, 2018c). Since 2000, over 900 ha of inter-tidal saltmarsh and mudflat have been created and a further 300 ha is being developed, therefore current estimates suggest a net gain of 296 ha based upon a 1994 baseline, although this does not include the large-scale losses before that baseline year. In addition, ca. 770 ha of reedbeds and coastal grazing marsh have been created in England since 2011.

Separate targets have been set for each main estuary complex, which are assumed as the minimum habitat needed to begin site recovery for designated sites (Royal Haskoning DHV, 2020). It is also recognised that more monitoring and evaluation is required to facilitate targeting and application of the 'Healthy Estuaries' tool may facilitate this although it requires whole estuary coverage of both LiDAR and bathymetry data.

Regional disparities in habitat creation remain and not all locations show a net gain in themselves, notably because much of the new habitat has been in the Humber estuary. It can also be identified that the primary focus has been intertidal habitat and freshwater marshes, with less emphasis on other habitats (e.g., saline lagoons, shingle features etc.). For vegetated shingle, the extent of losses incurred by the Folkstone to Cliff End Strategy (maximum length 10 km) and for the Dee, Solent, Hamford Water and the Humber remain to be quantified (EA, 2018c) and included in compensation planning at the time of the present CCRA.

A review of the effectiveness of site compensation measures (Morris *et al.*, 2016) has highlighted that more emphasis needs to be placed on the functionality of habitat creation rather than just its extent, and also the need for increasing consistency (including clear success criteria) in the approach to predicting the timescale for compensation to become functionally viable. This study noted that in the majority of cases a time lag occurred between the loss of Natura 2000 habitat and the point where compensation measures have become functionally effective. Monitoring had also largely concentrated on the compensation site, rather than on the whole Natura 2000 site.

#### 3.18.2.1.2.3 Northern Ireland

No equivalent initiative for habitat accounting and compensation has been identified for Northern Ireland, which further confirms an information deficit here when compared to other UK nations.

#### 3.18.2.1.2.4 Scotland

In Scotland, although Dynamic Coast has identified natural assets at risk of coastal erosion, plans to develop a strategic programme of habitat accounting or compensation remain at an early stage and currently no details of total habitat losses and gains are available at national scale through a verified reporting procedure (i.e., equivalent to the habitat compensation programmes reported for England and Wales). Intertidal habitat totalling 72.5 ha has been created to-date in Scotland. Habitat creation schemes at Nigg Bay (25 ha) and Skinflats (11 ha) both aim to redress historic losses from land reclamation, whilst Black Devon Wetlands (28 ha) also aimed to redress future coastal squeeze losses.

#### 3.18.2.1.2.5 Wales

In Wales, the National Habitats Creation Programme has projected habitat losses of 4663 ha by 2105 (assuming continuation of current rates of sea level rise) and is developing a strategy to replace these losses. The programme had created 459 ha habitat to 2018 and is proposed to be on target with plans for an additional 300 ha to offset losses identified within the 1st epoch of SMPs. However, most of the habitat creation has been in the Severn Estuary (elsewhere only 43 ha has been created, of which only ca. 15 ha is considered compensation for coastal squeeze). The available information does not distinguish between different types of habitats lost or created, or whether shingle, dunes and grazing marsh habitats are included. Analysis by Miles and Richardson (2018) also notes that although some estuaries (Dee, Severn) are shared with England, the figures and projections are inconsistent, again pointing to an underlying data issue for the coastal zone. In addition, there are challenges in separating out historic habitat losses from those which occurred since the 1990s when SMPs were implemented (Oaten *et al.*, 2018) and for which the 'no net loss' obligation is only assumed to apply by government.

#### 3.18.2.1.3 Addressing Cross-scale Issues and Climate Change Uncertainty

Forward projections of future habitat losses from coastal squeeze are challenged by multiple uncertainties, and even at present the monitoring of habitat changes associated with coastal squeeze has recognised limitations (Oaten *et al.*, 2018). Therefore, assessment of measures against concepts of 'no net loss' of coastal habitat remains difficult. One notable confounding factor is the influence of 18.6-year lunar nodal cycle on coastal water levels and hence habitat change. Hence, it has been suggested that monitoring needs to take better account of this (Oaten *et al.*, 2018).

A recent reappraisal of evidence has aimed to define a more consistent approach to coastal squeeze for use in SMPs in order to redress previous inconsistencies in how coastal squeeze has been evaluated (Pontee *et al.*, 2021). This report makes a distinction between habitats lost due to coastal defences and those that would have been expected to be lost anyway through inland habitat migration being constrained by steeply rising ground as a form of 'natural' squeeze (notwithstanding that anthropogenic climate change is the primary driver for sea-level rise). Based upon this distinction it is suggested that coastal squeeze losses attributed to coastal defences may have been overestimated, which has implications for habitat compensation obligations, although either way (i.e., defence-related or 'natural' squeeze) the habitat will be lost and the implications for policy responses to maintain and protect coastal biodiversity remain.

The long-term rate of sea-level rise is undoubtedly a key factor in projected losses and gains of priority habitats. Current habitat compensation requirements appear to be assessed based upon continued usage of rather old climate change data (originally from UKCIP98 data) and generic guidance for flood defence and SMPs (PAG3 guidance from the 1990s), rather than the latest data from UKCP18 (EA, 2018c; Oaten *et al.*, 2018). In addition, the plans cannot yet be considered robust when considered against higher projections of sea level rise, as re-emphasised by an increase in median and upper-level projections in UKCP18 data. A more robust response towards ensuring 'no net loss' would aim to create more compensatory habitat to provide 'headroom' to allow for uncertainties in sea level rise projections and other factors such as variability in the actual amount and quality of new habitat created. Furthermore, a more robust response would also consider habitat creation in the wider context of its integration with other habitat and the coherence of the ecological network as a whole. This is unlikely to be successful unless habitat creation initiatives also extend to cover historic losses that occurred before the advent of SMPs.

Further issues arise because habitat losses due to coastal protection structures can also occur in a downcoast position (as inferred in terms of the dominant direction of longshore drift) due to reduced sediment supply from eroded material, or sediment trapping in a specific location (e.g., from groynes or offshore reefs), involving both coarse and fine-grained material. In addition to downcoast intertidal habitat losses, this can affect dune systems from loss of beach sediment supply, and shingle bars. Increased rates of sea-level rise further modify these relationships, but they are yet to be fully incorporated into habitat availability assessments.

As highlighted above, in situ habitat resilience through accretion, or habitat migration due to realignment, can be strongly dependent on sediment supply which if depleted can exacerbate erosion and resultant flooding. Artificial recharge of sediments has now been implemented at several sites to facilitate natural adaptation, including for salt marsh restoration at realignment sites and to redress coastal erosion problems (e.g., at Montrose, east Scotland; or the 'Sand Engine' at Bacton on the Norfolk coast). However, such approaches require cautious identification of licensed sediment source areas in order not to move problems elsewhere.

#### 3.18.2.1.4 Institutional Challenges for Policy Implementation

Across all the UK, the coastal zone involves the interaction of multiple organisations with inter-related responsibilities. In locations where they have been developed, SMPs are intended to integrate national policy with the specific regional and local contexts of different sections of coastline (both biophysical and socioeconomic), but difficulties often occur in reconciling short-term development goals with long-term planning that effectively responds to climate change (Milligan *et al.*, 2009; Coates and Tapsell, 2019). Some stakeholders therefore actively resist a move away from maintaining structural coast defences in their current position, despite increasing evidence of the need for alternative approaches (Esteves and Thomas, 2014; Day *et al.*, 2015) and this can reinforce existing institutional decision-making processes that define hard engineering structures as the 'normal' solution (Harries and Penning-Rowsell, 2011; Challies *et al.*, 2016; van Buuren *et al.*, 2018)). Consequently, there is evidence of typically a default preference for a Hold the Line policy in practice and hence there is still limited implementation of strategies such as managed realignment that

would aim for a more sustainable long-term response (Brown *et al.*, 2017) meaning that coastal defence structures are prioritized over the viability of coastal ecosystems (Cooper *et al.*, 2016). Analysis has also shown that a flexible adaptive approach to setting allowances for sea-level rise in SMPs (and coastal CFMPs), as consistent with the uncertainty in climate change science, has met with resistance in coastal engineering because of the perception that decision making be seen to be based upon a more definitive interpretation of risk (Kuklicke and Demeritt, 2016).

This contradiction between aspirations and actual implementation occurs despite the intention that SMP policies are evidence-based documents. This is sometimes due to inconsistencies in collating and interpreting evidence through the SMP, but more often because of the challenges in reconciling local preferences for the status quo (as expressed by specific stakeholders) with the options as determined by the available evidence that increasingly indicates that the status quo is untenable (Brown *et al.*, 2017; Coates and Tapsell, 2019). Similarly, whilst current aspirations following the SMP Refresh are that SMPs become 'living documents' that are regularly reviewed, in practice there are often institutional barriers (e.g., resource constraints: see House of Commons, Environment, Food and Rural Affairs Committee, 2019) that act against a regular review process. This has meant that SMPs have previously not been systematically assessed in the light of new knowledge or wider policy changes that would often further imply the need for changes in preferred management option.

Nevertheless, it is also appropriate that positive examples should also be highlighted, as with those authorities that have brought together their planning policies under the auspices of Coastal Partnership East (in England) as part of their joint agreement. Similarly, some regional coastal groups have provided an active forum for knowledge exchange across multiple partner organisations which also has benefits for delivering integrated strategies (e.g., Southern Coastal group and SCOPAC for southern England). Similarly, cross-scale interactions are a key focus for the Scottish Coastal Forum which acts as a knowledge exchange mechanism for the five local coastal partnerships in Scotland, and at a more local level for the Pembrokeshire Coastal Forum in Wales which has placed a strong emphasis on community engagement. Further discussion of these contextual issues is provided in the 'Barriers' section (3.18.2.5).

### 3.18 2.2 Effects of Non-government adaptation (N17)

The influence of non-government actions is rather varied depending on local contexts. There are some notable model exemplars in which a long-term strategy has been developed and a transitional plan implemented to facilitate a progressive shift from the current position to this new strategy, typically including a planned shift towards either managed realignment or no further active intervention in order to protect or create new coastal habitat. These examples are most often small-scale and promoted by NGOs together with other interested partners, although the scale of ambition is increasing. A particularly notable lead is being provided by the National Trust, one of the UK's largest landowners, through its 'Shifting Shores' initiative, which establishes a consistent blueprint for adaptive coastal management across all its coastal properties. These positive examples of planned adaptation contrast with those from other local contexts where the approach remains dominantly reactive and for maintaining the status quo, whilst also pushing the difficult decisions into the future (e.g., House of Commons, Environment, Food and Rural Affairs Committee, 2019)

despite the high likelihood of greater long-term consequences from exacerbated climate change risks.

### 3.18.2.3 Barriers preventing adaptation (N17)

Despite some successful examples where new local policies have been developed, there is often considerable inertia in the planning system which favours the status quo, and coastal local authorities are often too under-resourced to take on the significant challenge of developing and implementing new coastal plans that have many interacting complications. In addition, responses are often still localised and dominated by local stakeholder preferences, rather than being set within the regional-scale framework, which was one of the key original objectives of SMPs so that responses at one location do not result in negative impacts being transferred to and exacerbated at other locations in a downcoast situation (Ballinger and Dodds, 2020).

Piecemeal responses can also be a significant barrier. As highlighted most notably for Northern Ireland (Cooper *et al.*, 2016), but also occurring in other parts of the UK (e.g., Brown *et al.*, 2017), shoreline management is still typically considered on a case-by-case basis with little regard to the cumulative effects and the need for a strategic approach to coastal protection. An especially notable barrier for proactive adaptation occurs in response to extreme events, when the recommendations made in SMPs that indicate a transition is required towards a more sustainable coast can in practice be ignored in favour of reinforcing defences in the same location and maintaining a HTL approach as a form of reactive adaptation, therefore perpetuating existing vulnerabilities (Brown *et al.*, 2017). At a more basic level, some parts of the UK, involving most of Scotland and all of Northern Ireland, do not have SMPs or an equivalent strategic procedure that can embed long-term cross-scale planning into local and regional decision-making.

As reported in previous CCRA, the current system for funding coastal protection schemes has also been criticised for also indirectly supporting a bias towards hard engineering schemes to protect built environment or infrastructure assets that can be assigned the largest cost-benefit ratios in monetary terms. This has further contributed to loss of coastal ecosystems from implementation of coastal defence structures (Cooper *et al.*, 2016). These institutional barriers may be at least partly attributable to the inherent challenges in monetising benefits from the natural environment, and also due to the use of engineering design concepts such as ‘standard-of-service’ criteria for coastal protection schemes which are less applicable for dynamic natural habitats and landforms. Emphasis is also placed by government on partnership funding which requires additional sources for co-funding, but there have been significant challenges in engaging private partners in schemes in recent years (House of Commons, Environment, Food and Rural Affairs Committee, 2019).

Current management plans can also be inconsistent and inadequate regarding the multiple benefits that coastal habitat can provide, including for hazard alleviation, amenity value or carbon storage (e.g., Ballinger and Dodds, 2020). Although there is increased recognition of the advantages of nature-based solutions, in practice other socioeconomic factors, typically related to development pressures or preferences of some stakeholders for the status quo, act against this type of initiative at present. For managed realignment schemes, issues related to land ownership and purchase can be difficult to resolve, and the economic case difficult to justify under current funding arrangements. As referred to above, good practice in habitat compensation schemes is being developed (e.g., the

REACH program) but there are often financial barriers to implementing this good practice which is likely to result in a less satisfactory outcome for new habitat schemes.

Another important barrier to effective adaptation is the constraints imposed by inadequate data availability for the coastal zone. A recent report by ONS (2016) identified the following general issues that have hindered natural capital accounting, but which are also very relevant as major impediments regarding progress reporting for adaptation objectives:

- Wide variation in the methodologies, habitat classifications and definitions used to develop accounts for coastal margins, meaning that national summaries vary widely. There is a requirement for improved datasets to be produced using standard habitat classifications and definitions.
- Severe data limitations on the physical extent of coastal margins, except for some protected areas, and also that existing data lack consistency and comparability. Assessments from Northern Ireland are highlighted as particularly lacking.
- The Biodiversity Action Reporting System data for many habitats and countries is based on very outdated surveys.

In operational terms, in our view, another current barrier to strategic-scale intervention is the arbitrary distinction of erosion and flooding hazards rather than to assess them together to develop an integrated approach, as consistent with the original concept of SMPs.

#### 3.18.2.4 Adaptation shortfall (N17)

In conclusion, our assessment is that adaptation is not occurring at a speed and scale to match the climate change risk to coastal habitats and species, both present and future. This is occurring despite government commitments in general towards establishing a sustainable coastline, and an increase in efforts to address this challenge. Priority habitats and species continue to be lost and ecosystem services degraded, although the impacts are variable when related to different policy indicators. Furthermore, in those administrations (England, Wales, and partially for Scotland) that have developed more explicit adaptation commitments through strategic initiatives such as SMPs and habitat compensation schemes, there is not enough evidence at present that these plans have been designed to be robust to climate change, as for example against higher projections of sea-level rise. A related issue is that monitoring of coastal change and of management interventions needs to be made more systematic and consistent to provide the improved quality of information necessary to understand the benefits from adaptation as related to different management options.

The reasons for this adaptation shortfall are also related to the continuing legacy of past decisions, which become increasingly ineffective as the magnitude of climate change increases. Adaptation on the coast involves some very difficult decisions and trade-offs, but our assessment suggests that these decisions may be being pushed into the future rather than addressed now, despite the increased consequences from climate change and rising sea levels. A range of positive examples of planned adaptation do now exist, facilitating both habitat restoration and transition (notably for intertidal habitats), including those led by NGOs and other groups, but these are predominantly local-scale and will be insufficient to fill the national and UK-wide adaptation shortfall as required to

manage risk down to low magnitude levels, both for present and future. Data and evidence limitations at national scale (especially for Northern Ireland) mean confidence in the assessment of adaptation actions with regard to risk management is low. These data limitations should also be addressed as a key component of progress assessment for policy delivery.

### 3.18.2.5 Adaptation Scores (N17)

**Table 3.59** Adaptation Scores for risks and opportunities to coastal species and habitats due to coastal flooding, erosion, and climate factors

Are the risks and opportunities going to be managed in the future?			
England	Northern Ireland	Scotland	Wales
Partially (Low confidence)	No (Very low confidence)	Partially (Low confidence)	Partially (Low confidence)

### 3.18.3 Benefits of further adaptation action in the next five years (N17)

#### 3.18.3.1 Nature-based Solutions (N17)

As highlighted above, the additional benefits of adaptation are strongly associated with further development of schemes to deliver a sustainable coastline throughout the UK, including through managed realignment as a form of nature-based solution. Additionally, allowing coastal evolution through a decision for ‘no active intervention’ may also enable a more sustainable outcome for the coastal zone. In some circumstances, it may be appropriate to integrate these nature-based responses with structural defences or soft-engineering responses (e.g., sediment nourishment) to combine protection of settlements and infrastructure with protection of the natural environment. The benefits of such actions should include improved recognition of the synergies achieved from restoring and protecting coastal habitats, both for their biodiversity value and for their ecosystem services, notably in providing additional resilience against flood and erosion hazards, and for carbon storage. Setting a clear target for priority habitat creation at national scale would be one policy mechanism to encourage further action, including also monitoring to ensure that good quality habitat is created.

An indicative measure of extended adaptation ambition, including greater adoption of nature-based solutions, has been provided by the CCC Floods study (Sayers *et al.*, 2020) in terms of the reduced flood risk for nature conservation assets (Table 3.60) which can be compared with existing adaptation (Table 3.58) or no further adaptation (Table 3.56). In this context ‘enhanced adaptation’ objectives were defined based upon specific assumptions linked to the scope for managed realignment (see Sayers *et al.*, 2020 for a full description of this adaptation scenario), and following this rationale shows added adaptation benefits are especially realised for England with little difference for Scotland and Northern Ireland (although these country-level differences may also be an outcome of the project assumptions regarding the focus for enhanced adaptation which may be more applicable to some locations). Decisions are also more complex than this in reality because some coastal wetlands (or other habitats) may be able to accommodate additional coastal flooding

whereas for others it may be detrimental, as influenced by key variables such as the extent and duration of saline inundation. In addition, if managed realignment is implemented to set back the defence line and maintain or enhance intertidal habitats then there could be additional benefits in terms of the additional flood and erosion protection provided by those habitats; for example, modelling analysis has indicated that for every kilometre of tidal flat (ranging from high marsh to bare tidal flat), coastal defences can be notionally lowered by 0.84 m–0.67 m when designing for a 1-in-200-year storm event (Zhang *et al.*, 2021). Hence, further and more detailed investigation of these adaptation issues is therefore required to confirm the initial results of Sayers *et al.* (2020), including against a wider range of assumptions and scenarios, and for England the enhanced adaptation commitment implied by the National Flood and Coastal Erosion Management Strategy (EA, 2020; HM Government, 2020).

**Table 3.60** Change in nature conservation assets at significant risk of coastal flooding (frequency of 1-in-75-year or greater) for the 4 nations assuming an extended level of adaptation (Sayers *et al.*, 2020).

### 3.18.3.2 Habitat Creation Opportunities (N17)

To help achieve a higher of ambition for adaptation of coastal habitats and species requires a more detailed systematic survey of habitat opportunities across the UK to update the existing, mainly smaller-scale surveys. In terms of indicative potential, a recent high-level study (Miles and Richardson, 2018) identified 34250 ha of potential intertidal habitat opportunity for the UK, including at priority level 52 potential projects which could contributing 13450 ha of habitat. Obviously, further work is necessary to cross-validate such estimates for their robustness using more detailed source data (e.g. high-resolution topographic data is known to make a substantial difference for low-lying coasts) and against future climate change projections (notably for sea-level rise). In addition, more consistent and robust approaches to record habitat losses and gains are required (including all priority habitats and not confined to designated areas). In England, a broad-scale assessment of potential restoration/recreation sites for intertidal habitat has been developed, which could also provide a basis for more detailed appraisal and implementation at local level (MMO, 2019).

### 3.18.3.3 Integrated Approaches to SMPs and other Plans (N17)

This information also needs to be integrated with current activities to refine and update SMPs (including the SMP Refresh) in order that habitat protection and creation is factored into long-term strategic decision-making. This integration would also be further strengthened by stronger and consistent linkages between SMPs and Flood Risk Management Plans so that the interaction between erosion and flooding hazards are better managed together.

In England, there is a relevant commitment in the new government flood risk policy statement to reform local flood and coastal erosion planning by 2026. It has been suggested through feedback into the CCRA that the wording in both the Flood and Water Management Act 2010 and the Coast Protection Act 1949 (CPA) require adjustment to take into account the need for an integrated approach in the light of climate change impacts. Similar policy adjustments have also been identified for the DAs. Whilst we recognise that current policy developments aspire to deliver a more integrated approach to coastal management, it is not clear how this will overcome the considerable existing barriers identified above, especially when integrating across scales between local, regional and national objectives, and specifically for more sustainable outcomes for the natural environment. In this context, the key transformation challenge remains as policy implementation for a sustainable coastal zone rather than developing high-level policy guidance.

### 3.18.3.4 Monitoring Programmes (N17)

Adaptation would also strongly benefit from continuing and improved coastal monitoring programmes. A shift away from a reliance on hard engineering towards soft interventions, including nature-based solutions, would be reliant on such complementary monitoring initiatives for success. A third phase of the National Network of Regional Coastal Monitoring Programmes is now in progress including asset monitoring for the next 6 years, and there are plans in England for a second national saltmarsh survey. Improved monitoring could also be achieved through increased support for Coastal Observatories (currently 6 regional programmes in England and Wales) including complementary initiatives in Scotland and Northern Ireland.

As recognised by the Dynamic Coast project in Scotland, an upgrade in data quality to 3D time series would provide a step change in understanding the local coastal sediment budget and, crucially, identify areas of sediment loss and gains. This would require whole-coast acquisition of regularly updated 3D time series data of habitat and landform change (e.g., via airborne LiDAR) and better availability of bathymetry and wave data. Further benefits would also be achieved through consistent development of national datasets for natural and artificial coastal flood/erosion defence structures across the UK and for improved understanding and consistent use of coastal sediment budgets in SMPs.

#### 3.18.3.5 Adaptive Management and Adaptation Pathways Approaches (N17)

Ultimately, the strategic direction of SMPs and other coastal plans need to be refined to recognise that future climate change and rates of sea-level rise are inherently uncertain, and hence that flood and erosion management would benefit from an approach that defines multiple adaptation pathways, with the preferred option then related to the magnitude of climate change. The added value of improved monitoring here would be to help steer the right path for shoreline management planning and managed realignment policies based upon up-to-date data. The policy process is beginning to recognise the importance of this adaptability for coastal zone management, but at present, with the exception of very specific examples (e.g., the Thames Estuary 2100 project), there is a lack of examples that we have seen of pathways feeding into strategic coastal plans and of how target outcomes (e.g., habitat creation targets) would be redefined across multiple pathways.

#### 3.18.3.6 Indicative costs and benefits of additional adaptation (N17)

There are some studies which include the impacts (in economic terms) of climate change on some coastal habitats notably wetlands (e.g., see Brown *et al.*, 2011; Schuerch *et al.*, 2018), but these studies do not assess the costs and benefits of adaptation. There are also studies that look at the role of coastal ecosystems for ecosystem-based adaptation, with analysis of costs, cost-effectiveness analysis and cost benefit analysis (Narayan *et al.* 2016; ECONADAPT, 2017; McVittie *et al.*, 2017). However, there is much less information on the costs and benefits of helping coastal species adapt, and there may also be trade-offs with measures to protect the built environment having consequences on species (coastal squeeze). Early low-regret options tend to focus on improved information and monitoring, but there are other measures including possible reinforcement or enlargement of existing measures, e.g., protected areas, buffer zones, as well as restoration of areas or managed realignment, and there are some estimates of restoration costs from previous projects.

#### 3.18.3.2 Overall urgency scores (N17)

As with CCRA2, the urgency assessment for this risk (and unrealised opportunities for habitat creation) is that of 'More Action Needed'. This urgency should be further emphasised by the elevated sea-level rise values in UKCP18 and other projections compared to those underpinning CCRA1 and CCRA2, and by the long lead times expected to restore a sustainable coastline, including for the full range of species, habitats and ecosystem services that nature-based solutions can deliver. A key step in delivering this agenda will be to reinforce shoreline management planning or equivalent strategic planning procedures as implementation mechanisms to bridge between national and local goals based upon a robust interpretation of climate change and coastal science. Habitat restoration and compensation schemes need to be fully aligned with this goal rather than

treated as add-ons, and this will require much stronger emphasis on addressing current implementation barriers at local and regional level.

<b>Table 3.61</b> Urgency Score for Risks and opportunities to coastal species and habitats due to coastal flooding, erosion, and climate factors				
<b>Country</b>	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	More action needed	More action needed	More action needed	More action needed
<b>Confidence</b>	Medium	Low	Low/Medium	Medium

### 3.18.4 Looking ahead (N17)

The following information would be useful for CCRA4:

- In addition to sea-level rise, improved assessment of other coastal drivers at local/regional scale including waves and tidal dynamics, and additionally for estuaries to include changes in freshwater inputs (fluvial flows).
- Large-scale opportunity assessment of managed realignment based upon multiple benefits (e.g., using an ecosystem services framework – see section 3.21.3) and a range of sea-level rise scenarios, placing small local schemes in a regional context.
- Assessment of current habitat change for all priority habitats and future habitat change based upon a diverse range of climate change and management scenarios.
- Species and ecosystem function assessments for managed realignment and habitat restoration schemes to monitor ongoing change and progress in terms of their resilience against climate change.
- Integration of the above recommendations with the current SMP Refresh and equivalent SMP processes for all the UK to show the links between evidence, policy, and implementation actions under different adaptation options and pathways (e.g., as defined by different sea-level rise scenarios).
- Further use of the ecosystem services framework to provide stronger links between this chapter and the risks and opportunities defined by other CCRA chapters.

- A unifying issue for all of the above recommendations is the need for improved consistency in monitoring and change assessments (e.g., using a common protocol) to facilitate better transparency in adaptation progress reporting across all the UK.

### 3.19 Risks and opportunities from climate change to landscape character (Risk N18)

- Future changes to landscape character will occur from a range of natural responses to a changing climate including biodiversity, soils, geomorphology, hydrological processes, and coastal processes.
- Landscape character will also be modified by indirect effects of a changing climate, notably through land use change, and there are important interactions with cultural heritage (Chapter 5: Kovats and Brisley, 2021).
- Risks and opportunities from climate change for this topic are assessed as increasing in magnitude from medium (present) to high (future).
- Current adaptation plans for all 4 UK nations for this topic are limited, although there are some important developments at local level that show increasing recognition of the issues and the added value from linking adaptation and landscape change with the Net Zero agenda.
- Nevertheless, assumptions are generally made based upon a single climate change pathway and current plans cannot be considered to be robust against the full range of possible future climate change impacts, especially at the upper end of projections.
- Further development and use of landscape character in planning will help raise awareness and understanding of risks and opportunities of climate change (including interactions with Net Zero pathways), particularly regarding how people relate to landscapes as places to live, work and enjoy.

#### Introduction

This topic is broadly defined to include risks and opportunities relating to landscapes, representing the combined effect of other risks and opportunities from CCRA Chapter 3 with an important link also to the historic environment and cultural heritage (Chapter 5, Risk H11: Kovats and Brisley, 2021). Due to the integrated effect of other risks and opportunities at landscape scale, we assess this topic as increasing in magnitude from medium at present to high in future, especially with higher climate change scenarios. Loss of natural features and phenomena that contribute to landscape character includes both economic impacts and less tangible issues that impact on people's well-being in many diverse ways. Expert opinion has been used predominantly, therefore, in this assessment.

Some important recent initiatives have shown how adaptation could be integrated with landscape concepts, but evidence is still limited. Based upon this current position, we recommend further investigation, trialling, and support for these approaches. This may also have added value in providing a mechanism to bridge between national policies and place-based approaches that

recognise each area's own distinctive landscape assets, whilst also engaging with people who value landscapes in their own individual way, in turn providing a key link between the natural environment and human well-being (Chapter 5: Kovats and Brisley, 2021).

The European Landscape Convention (ratified by the UK) defines a landscape as, *"an area, perceived by people, whose character is the result of the action and interaction of natural and/or human factors"*, putting emphasis on the whole landscape and its multiple values, whilst also recognising its dynamic properties. Landscape character has been formally defined as *"a distinct, recognisable and consistent pattern of elements that occur in a particular type of landscape..... Character makes each part of the landscape distinct and gives each its particular sense of place"* (Natural England, 2014). Landscape functions represent goods and services provided by the landscape as a whole, or key elements within it, and include less tangible properties such as 'a sense of place' that contributes to local identity. Elements contributing either to overall character or specific functions may be recognised as important assets (natural or cultural). Integral to all these definitions is that landscapes, to varying extents, bring together both natural features and cultural elements that represent the interaction of natural processes with the legacy of people (Chapter 5, Risk H11: Kovats and Brisley, 2021 ) in a specific area.

Using broadly similar approaches across the UK, Landscape Character Assessment (LSCA) has then identified and described a wide variety of different character areas. Each of these has its own distinctive characteristics based upon combinations of geology, landform, soils, vegetation, land use, field and settlement patterns (also including the 'seascape' dimensions of coastal areas) and a range of functions that collectively define a multifunctional landscape (Figure 3.17). In addition to their distinctive visual, aesthetic, and historic associations, landscapes also act as the geographic settings for distinctive local produce and customs, notably local food and drink. Some landscapes are also highly valued for their special qualities of 'natural beauty', which is a key legislative characteristic used for designating National Parks (National Parks and Access to the Countryside Act 1949) or Areas of Outstanding Natural Beauty (AONBs: Countryside and Rights of Way Act 2000) and reaffirmed as a key characteristic in the recent Glover Report (Glover *et al.*, 2019). In Scotland, landscape qualities are key components of National Scenic Areas (Planning (Scotland) Act 2006; Town & Country Planning (NSA) (Scotland) Designation Directions 2010) and Scottish Planning Policy 2014 requires appropriate consideration to both designated areas and landscape character. These qualities and features, individually and collectively, may be influenced by climate change (as they have done in the past). The advantage of considering them in a landscape character perspective is the use of a holistic framework and that it can include less tangible characteristics such as sense of place and identity that have been under-represented in climate change decision-making (Adger *et al.*, 2011).

It is very likely that EU-exit will have significant implications for this topic, perhaps most notably through changes in land use that occur as a consequence of modified trade agreements and the transition towards new policy and regulatory frameworks. It is also quite possible that the current Covid-19 pandemic may have ramifications for this risk, such as increased awareness of the value of local landscapes. In both cases, however, we have very limited evidence on how these issues may develop in the future and how they will interact with climate change risks.

### 3.19.1 Current and future level of risk and opportunity (N18)

#### 3.19.1.1 Current risk and opportunity (N18)

This topic is considered in terms of both risks and opportunities because of the varying subjective interpretations of landscape change amongst different people and groups. CCRA2 previously defined this as a topic requiring a 'Watching Brief' based upon a process of monitoring impacts and accounting for climate change in future landscape character assessments. Since then, although little primary research has been published, further developments and a greater recognition of landscape character in related issues allows a more refined assessment to be made of the current status. These developments include the inclusion of aspects of climate change in influencing key landscape elements and their functions, and therefore collectively in modifying landscape character, as recognised by adaptation strategies (see 3.19.2 below) produced through local plans for National Parks, local authorities, NGOs and some other major landowners in the UK.

The impacts of extreme events, such as flooding, drought or storm damage, in addition to incremental climate change such as the influence of climate warming on vegetation patterns, have been recognised in some local landscape assessments. Examples of impacts include major changes in coastal areas due to sea level rise and storm events (Risk N17) that have been associated with

flooding and erosion (e.g., North Norfolk: Land Use Consultants, 2019). Impacts on terrestrial ecosystems and habitats (Risk N1) include changes in drought-prone woodland and downland communities in south-east England (e.g., South Downs National Park, 2020) and the poor flowering of heathlands habitats in both 2018 and 2019 as a consequence of excessively dry conditions in summer 2018 and an increase in heather beetle damage (reported anecdotally from several locations including Exmoor, Shropshire and the North Pennines). For freshwater habitats (Risk N11), warmer temperatures have been associated with an increasing incidence of eutrophication, which degrades functioning and amenity value; related issues have been identified throughout the UK including the Lake District, Loch Leven (Scotland) and Lough Neagh (Northern Ireland). In agricultural landscapes, climate-related changes in land use patterns, such as new cropping systems and livestock housing, have to a varying extent modified the traditional character of these landscapes (Risk N6 and Risk N9), as for example identified in Wales (Berry *et al.*, 2019). Some of these impacts have occurred through the combined effect of climate and land use change.

Landscapes have also been modified by the increased incidence of large-scale wildfires in recent years, notably in 2018, 2019, and 2020 (Belcher *et al.*, 2021; see also Box 3.1 in Introduction), and due to drier conditions (e.g., drought during summer 2018). It is possible that the damage will only be temporary as vegetation becomes re-established but also that the loss is irreversible as the disturbance leads to the development of new ecological communities that are more suited to the changing climate at the site. Nevertheless, these changing conditions may also provide opportunities regarding improved knowledge of past environments and people's relationship with them. For example, the Royal Commission on the Ancient and Historical Monuments of Wales (RCAHMW) identified approximately 100 new historic assets during the severe summer drought of 2018 due to the different soil moisture patterns.

Although there are many studies on individual landscape elements, we still have rather limited evidence on the impacts of climate change across the landscape mosaic as a whole, including how climate has interacted with other (socioeconomic) factors. In addition, we also have limited evidence on how these changes have influenced perceptions of landscapes across different user groups.

An important example of these inter-relationships is the interaction of climate change with traditional land management approaches that are integral to the landscape character of many areas of the UK, and often a unique synergistic combination of the natural environment with cultural heritage. Amongst many noteworthy examples may be highlighted hay meadows, water meadows, coppices and orchards, upland moorland habitat mosaics, and some parklands, which can each have a high landscape and biodiversity value that is maintained by traditional practices. A key component of these land management practices is adaptation, in a generic sense, to changing conditions, including variable weather and climate, but there is rather limited information on how these autonomous adaptation responses are (or are not) adjusting to the climate change occurring now, and the challenges this involves with regard to continuing such practices.

### 3.19.1.2 Future risk and opportunity (N18)

Assessing future change for this topic involves considerable uncertainty because it represents the interaction of several other risks (as described above), strong relationships with the magnitude of climate change and socioeconomic change (including policy goals), and diverse interpretations of risk and opportunity compared to the current landscape and its functions. Landscapes are the dynamic outcome of multiple elements, some of which may be considered more dynamic compared to others, meaning response times to climate change (and other drivers) will vary. Better information on these relationships will be important in influencing managed change as distinct from unmanaged outcomes, although it is also possible that some landscapes are 'left to nature' within a 're-wilding' paradigm to also help better understand the response of natural processes to change. Therefore, although we have improved information from specific landscape locations, large-scale assessment of future landscape change remains at lower confidence, although the evidence does allow some inferences on those at higher likelihood of change (e.g., some upland landscapes, lowland agricultural landscapes, coastal landscapes etc.).

As identified elsewhere in this assessment, future changes to landscape elements will occur from natural responses to a change climate through biodiversity (N1 and N3), soils (N4), hydro-ecological processes (N11 and N13), and coastal processes (N17). Changes will also occur through land management responses to climate change, such as new crops or agricultural intensification (N6 and N9), or more substantial changes in land use (e.g., agriculture to forestry), or in some cases through a planned shift to a previous or new state (e.g., floodplain restoration, managed coastal realignment). In addition, future climate change is very likely to bring an increased risk from pests, pathogens and invasive species (N2, N7, N8, N12 and N16). An assessment of potential changes in the Welsh landscape (LANDMAP) using expert judgment has identified how this could bring about a change in many distinctive landscape mosaics (Berry *et al.*, 2019). For example, the presence of wetlands in the landscape may be significantly modified by drought frequency and agricultural landscapes by new crops and management practices. In landscapes that include woodland as a key feature, the presence and mix of tree species is likely to change, possibly including a reduction in some broadleaved species, such as oak and ash. However, there are notable uncertainties associated with undertaking future predictions due to the interaction of climate change with multiple biophysical factors (ecological, hydrological, geological, geomorphological, pedological) and socioeconomic factors (land use, culture, leisure activities etc.). Possibly more realistically, an assessment framework that explored different future scenario pathways may be a more practical decision framework to investigate the relationship between controllable and less controllable aspects of landscape change, including how they relate to target outcomes and public preferences.

Some landscape changes may be less gradual, such as irreversible changes to vegetation communities following an expected increased incidence of drought. In addition, the prospect of increased frequency and severity of abrupt extreme events such as wildfire also increases the likelihood of some valued landscapes being significantly modified.

An important development since CCRA2 is that some studies are now further developing the practical use of LSCA in a climate change context. In Wales, the LANDMAP study (Berry *et al.*, 2019)

has used a high-level approach to qualitatively assess climate change risks for generic landscape types and the resulting strategic planning implications for specific places and their distinctive characteristics. This also provides a strategic framework for monitoring programmes to better inform actual processes of change rather than generic statements.

Furthermore, more information is becoming available on the geodiversity components of landscape in addition to biodiversity. For example, analysis in Scotland found 80 (8.8%) of the 900 nationally and internationally important geoheritage sites are at 'high' risk from climate change based upon UKCP09 climate data (Wignall *et al.*, 2018). These at-risk features include active soft-sediment coastal and fluvial features, finite Quaternary sediment exposures and landforms in coastal and river locations, active periglacial features, sites with palaeo-environmental records, finite or restricted rock exposures, and fossils.

#### 3.19.1.3 Lock-in (N18)

The primary lock-in risk is associated with a presumption for attempting to maintain landscapes exactly as they are now or to restore them to some historic previous condition, regardless of present and future climate change.

#### 3.19.1.4 Thresholds (N18)

As identified in the other Chapter 3 risks that each contribute to this aggregated risk/opportunity, there are important climate-related thresholds, the crossing of which may produce irreversible landscape change. Important examples of this are changes in semi-natural vegetation (e.g., from blanket bog or heathland to grassland; between woodland types; or between coastal habitats) although these are more usually related to the combination of multiple climate parameters rather than just one in isolation (also including the rate of sea-level rise for coastal landscapes).

#### 3.19.1.5 Cross-cutting risks and inter-dependencies (N18)

This topic acts to integrate many of the other risks in this chapter (depending on landscape context), whilst also having important interdependencies with cultural and historic heritage as recognised through many designated sites. In addition, changes in landscapes can have complex effects on individual and collective well-being, such as through the association between 'sense of place' and identity, as for example recognised in the diagnosis of 'solastalgia'-type negative impacts on people due to loss of cherished landscape features (Cunsolo and Ellis, 2018, Tschakert *et al.*, 2019).

Linkages with cultural heritage and the historic environment also indicate that further use of archaeological evidence could be advantageous in improved understanding of local landscape contexts, especially for understanding variability of risks and risk management through time.

#### 3.19.1.6 Implications of Net Zero (N18)

There are very important landscape-level interactions with the Net Zero agenda, especially as the latter is predicated on major land use changes (e.g., woodland expansion; agricultural

intensification; renewable energy installations) and lifestyle changes (e.g., diet; modes of transport; working patterns including homeworking). Landscapes will therefore be impacted by drivers for change from the biophysical effects of climate factors, and from the socioeconomic effects of both climate change adaptation and mitigation responses, acting together. With regard to landscape character, this presents both risks, especially when the different drivers act against each other, or opportunities when they are more synergistic, as may occur through landscape restoration and rehabilitation.

#### 3.19.1.7 Inequalities (N18)

As noted above, landscape change and modifications of landscape character are important because they represent a key component of the relationship between the natural environment and people, as also associated with cultural benefits and cultural heritage. These relationships are fundamentally subjective and therefore can affect individuals or groups of people in very different ways. In addition, there is increasing research showing that interaction of people with landscapes, or a local greenspace within that landscape (e.g., in an urban area), is beneficial for human well-being and quality of life, and by implication that loss of that interaction can have negative consequences, although relationships are often complex (Capaldi *et al.*, 2015; Wendelboe-Nelson *et al.*, 2019; see also section 3.21.3 and Chapter 5, Kovats and Brisley, 2021). We can therefore assume that changes to landscape character will very likely have implications for addressing societal inequalities, although at present there is very limited evidence that directly engages with this issue.

An important issue to recognise, including in a climate change context, is that all landscapes matter and have their own distinctive qualities, as emphasised by the Landscape Convention statement referenced above. These qualities are therefore not exclusive to designated areas with regard to interactions between climate change and societal inequalities. This needs to be recognised in policy support for inclusion and engagement, especially of local people, across the full range of UK landscapes.

#### 3.19.1.8 Magnitude scores (N18)

Magnitude categories are based on expert judgement as related to existing and expected impacts across the wide diversity of UK landscapes and landscape types (as also informed by other risks in this chapter that aggregate at landscape scale). Landscape character is a descriptive terminology therefore quantification is more constrained for this topic. Risk magnitude is assessed as increasing from medium at present to high in future with the exception of 2050 under the lowest climate projection when the magnitude of change may not be as pronounced. However, confidence is low for all of this assessment due to the limited evidence available, especially when referenced against CCRA risk categories. It should also be noted that here we are assessing climate-related magnitudes of change for landscape features; whether these represent risks or opportunities involves subjective judgements and are therefore not further distinguished.

**Table 3.62** Magnitude score for risks and opportunities from climate change to landscape character

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	Medium	Med-High	High	High	High
	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Northern Ireland</b>	Medium	Med-High	High	High	High
	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Scotland</b>	Medium	Med-High	High	High	High
	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)
<b>Wales</b>	Medium	Med-High	High	High	High
	(Medium confidence)	(Low confidence)	(Low confidence)	(Low confidence)	(Low confidence)

### 3.19.2 Extent to which current adaptation will manage the risk and opportunity (N18)

#### 3.19.2.1 Effects of current adaptation policy and commitments on current and future risks (N18)

##### 3.19.2.1.1 UK-wide

At national scale, there have only been limited further developments of adaptation policy in a landscape context since CCRA2, although the UK is a signatory to the European Landscape Convention. The appropriate national adaptation plans for each administration provide general statements of support and aim to improve awareness, but prefer to highlight positive local case examples rather than set out a national framework for achieving landscape-scale objectives. Guidance is provided by the national conservation agencies on Landscape Character Assessment (LSCA), which is increasingly recognising climate change risks and responses (adaptation and mitigation) (Natural England, 2014; Berry *et al.*, 2019). However, it is difficult to define and assess progress regarding the effectiveness of adaptation policy actions even with regard to the current climate, most notably because there is very limited reporting on progress, such as may be provided using indicators associated with landscape character. For this reason, we cannot currently say whether current adaptation plans for all 4 UK nations are robust against expected future climate change, especially at the upper end of the climate projections (4°C scenario etc.).

#### 3.19.2.1.2 England

The National Planning Policy Framework (NPPF) calls for valued landscapes to be protected and enhanced (NPPF para 109), with the greatest weight being given to conserving landscape and scenic beauty in National Parks and Areas of Outstanding Natural Beauty (AONBs) (para 115). An up-to-date LSCA is also recommended in the NPPF to support planning decisions by local planning authorities. The Landscape Recovery component of the proposed new Environmental Land Management (ELM) scheme (see Risk N1 for more details) has potential to deliver landscape-scale initiatives co-ordinated across multiple land managers for maximum benefit, although this is currently only at policy development stage.

#### 3.19.2.1.3 Northern Ireland

For Northern Ireland a comprehensive assessment of both the 26 regional landscape character areas and the 24 seascape areas identified on the coast has been previously conducted by DAERA. This provides a good reference base from which to assess changes in the key characteristics that define these areas, but the information is yet to be updated based upon current knowledge of climate change risks, such as by using UKCP18 or previous CCRA Evidence Reports. Similarly, plans for designated AONBs are yet to be updated with climate change adaptation strategies.

#### 3.19.2.1.4 Scotland

The second Scottish Climate Change Adaptation Programme (SCCAP2) mentions further development of landscape-scale initiatives, which may be also further facilitated through the place-based approach being further developed through the Land Use Strategy. Notable examples include the Central Scotland Green Network and landscape initiatives being developed in the Cairngorms National Park. NatureScot also intend to deliver a minimum of 15 capital projects across Scotland that improve or create at least 140 hectares of urban green infrastructure. Plans are also being developed to re-appraise climate change effects on landscape character as part of the action plan of collaborative tasks identified by NatureScot and Historic Environment Scotland (HES) through their 2019 joint landscape position statement 'People, Place and Landscape'. The work will review previous work from 2011 and potentially use it as a baseline with initial outputs anticipated in 2021. National Scenic Areas are also an important designation for recognising high-quality landscapes in Scotland and will provide an additional focus for defining local risks and opportunities. An associated initiative 'Building a Fire Resilient Landscape' is intended to promote awareness and changing practices regarding the changing risk from wildfires.

#### 3.19.2.1.5 Wales

The Welsh Government's Planning Policy sets out national land-use planning policies that acknowledge the issues; 'Distinctive and Natural Places' recognises that climate change is likely to have significant impacts on landscape character, historic buildings, local distinctiveness and quality. As noted above, the LANDMAP study (Berry *et al.*, 2019) is being used to develop a strategic framework for considering national-level policy and planning issues and their integration with local planning. Building resilience to climate change at a landscape level is built into SPG guidance in each

National Park, but mostly dates from 2014-15 and is therefore yet to be updated with new information such as from the CCRA2 Evidence Report or UKCP18. Some, but not all, AONBs do include CCRA2 risks in management plans, or aim to do so during an upcoming update phase. At regional level, Climate Ready Gwent is identifying landscape-related multi-partner opportunities to enhance local ecosystem and community resilience in the context of climate adaptation and mitigation. Regarding synergies with the historic environment, the Historic Environment Group (Climate Change subgroup) have led production of a Historic Environment Climate Change Sector Plan that is focused on climate risks to particular landscapes and historic assets in Wales and this has made some use of UKCP18 data.

#### 3.19.2.1.6 Landscape Character Assessment (LCSA) and Geoheritage Assessments

At local government level, use of LSCA in the conventional planning process is being utilised by some planning authorities as a mechanism for further integration of adaptation (and mitigation) decisions into the planning process. Hence, LSCA is used to gauge threats and opportunities to key assets and their functions together with a screening and prioritising of potential adaptation options in an integrative landscape character approach following general national guidance. Prominent examples developing this approach include the South Downs NPA Adaptation Plan, or the Warrington Borough Council climate change strategy. Some of these plans are also being further developed using concepts of ecosystem services and natural capital and are considering adaptation and mitigation initiatives in the context of enhancement of green and blue infrastructure. A prominent example in this context is the Clwydian Range and Dee Valley AONB Natural Beauty guidance on 'Working with a Changing Climate', which has adopted a place-based approach to climate adaptation to raise awareness and understanding of the potential effects of a changing climate within the designated landscape. The same AONB is also providing planning guidance on 'Landscape and Nature Recovery in a Changing Climate'.

In Wales, a follow-on project has further investigated the use of the LANDMAP study (Berry *et al.*, 2019) as a basis for considering both climate change impacts and adaptation and mitigation responses on landscape character and qualities, including as they relate to visual and sensory experience, as associated with 14 landscape types to 2050 (White *et al.*, 2020). The areas include open and wooded uplands and lowlands, coastal edge, built up areas and water. This approach may provide a model for considering how landscape character areas and types can be affected by the changing climate. Nevertheless, methodologies will probably need to be further expanded to include the ramifications of a transition from one landscape character type to another, especially in the context of higher magnitude climate change scenarios and potential threshold effects. For example, the present distribution of agricultural and wooded landscapes will almost inevitably have to change in future (see Risks N6 and Risk N9) in response to climate change as well as other drivers, including the implementation of policies to meet Net Zero.

LCSA also provides a basis to consider landscape sensitivity, which is usually defined as the combination of the susceptibility of change in a specific landscape (i.e., ability to accommodate change without major modification) together with the inherent value of that landscape (in terms of its multiple qualities including visual qualities). Landscape sensitivity is being further developed through guidance in England (Natural England, 2019) and similar guidance is now also being

prepared in Scotland and Wales. In several regards, the landscape sensitivity framework is similar to a risk assessment and therefore sensitivity assessments may allow a further integration of concepts that can inform adaptation decisions, including evaluation of multiple scenarios and adaptation pathways.

Similar methodologies are now also being developed for geoheritage conservation planning which also have important landscape implications (including through recognition of sites of high geodiversity importance, such as landforms or sediment/rock profiles). For example, climate change risk assessment in Scotland has been linked to prioritisation of management actions varying from 'do nothing' to moving boundaries, rescuing excavations, and posterity recording (Wignall *et al.*, 2018).

### 3.19.2.2 Effects of non-Government adaptation (N18)

In addition to local government initiatives, some NGOs are also using the LSCA framework to develop adaptation planning, both as a general strategic approach and for specific locations. Prominent examples include implementation by the National Trust to highlight the anticipated scale of future change and the associated scope to apply nature-based solutions to facilitate adaptation, notably on the coast where managed realignment or a policy of no active intervention implies major shifts in landscape (and seascape) characteristics.

As landscapes are the combined outcome of multiple stakeholders, including both planned and reactive responses, this approach emphasises the added value from a co-ordinated partnership approach to achieve collectively agreed outcomes that cover biodiversity, geodiversity and cultural heritage together. This should include plan development, placemaking and coordinated actions to maximise cross benefits and synergies. An important component of this integrated approach is the advantages of the landscape-based approach to consider risk interactions and cumulative impacts in order to minimise the potential for maladaptation. For example, the 'Living Landscapes' initiative represents a multi-partner approach (led by the Wildlife Trusts) to make space for nature following principles of landscape-scale conservation, including enhanced ecological cohesion and connectivity. Nature Improvement Areas (NIAs) are a network of large-scale initiatives developed in England to improve ecological connectivity and improve biodiversity, typically in areas that have previously experienced habitat degradation; they were launched in 2012 and currently cover just over 100,000 ha in total.

New techniques and revival of previous techniques are being trailed to facilitate restoration of valued landscapes following major disturbances such as wildfires. For example, stakeholder feedback to the CCRA has identified that in Wales, Cadw is testing grassland restoration and management techniques following catastrophic wildfires and severe drought in of 2018, including use of hydro-seeding.

### 3.19.2.3 Barriers preventing adaptation (N18)

Protecting and enhancing landscapes in the face of climate change requires improved awareness of the implications of both current and future climate changes and an inclusive discussion on what is

valued most in different landscape contexts, together with a shared recognition that landscapes are dynamic and some form of managed (or even unmanaged) change cannot be avoided. This is especially needed as some existing adaptation actions can be conflicting in a landscape context. A notable example is that flood/erosion defence schemes may reduce biodiversity value or landscape amenity value; such a relationship has been shown by a national-scale analysis that has indicated that rural house prices in areas with flood defence schemes are reduced by 0.8 to 5% which has been interpreted as dis-amenity value (and potentially flood redirection issues) outweighing perceived benefits from the flood defences (Beltrán *et al.*, 2018). Effective management of landscape change usually requires agreement and co-ordination between multiple stakeholders and this can often impede progress unless an active forum for negotiating issues already exists (e.g., catchment management partnerships or coastal management partnerships). Conserving landscape character and local distinctiveness in the face of external pressures (usually market-driven or policy-based) for significant changes in land use or management (e.g., intensification) is known to be difficult (UNESCO, 2003).

Information on public perception of change in the context of risks and opportunities at landscape level also remains limited and can act as barrier to further development of managed change.

#### 3.19.2.4 Adaptation shortfall (N18)

Despite a recognition by all administrations of the importance of landscape and some positive developments that are mainly for specific locations, it is difficult at present to distinguish effective adaptation responses, and there is very limited reporting on progress beyond awareness raising. At national scale, Wales is the nation that appears to have made most progress in addressing the issues through the strategic development of the LANDMAP project and related initiatives that explicitly include climate change. However, on the basis of the limited evidence available, current adaptation plans for all four UK nations cannot be considered to be robust against expected future climate change with regard to objectives for maintaining or enhancing landscape character, especially at the upper end of the climate projections. Evidence on adaptation actions and outcomes, including how these will interact with socioeconomic drivers and the Net-Zero agenda, is also very limited, hence confidence in assessing the adaptations shortfall is low.

#### 3.19.2.5 Adaptation Scores (N18)

<b>Table 3.63</b> Adaptation Scores for risks and opportunities from climate change to landscape character			
<b>Are the risks going to be managed in the future?</b>			
<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
Very Partially (Low confidence)	No (Low confidence)	Very Partially (Low confidence)	Partially (Low confidence)

### 3.19.3 Benefits of further adaptation action in the next five years

Improved collaboration between local and national government in developing a cross-scale planning framework for LSCA that integrates climate change responses (adaptation and mitigation) would be advantageous, as demonstrated by LANDMAP and related projects in Wales. This should also be linked with developments by NGOs and other pioneering organisations. Monitoring is an essential part of the management process to trigger evidence-based interventions. Landscapes also vary strongly in terms of their level of human management, from wild land which may be close to a pristine natural environment to designed landscapes which have been heavily modified and managed to enhance their cultural heritage. It is possible that some designed landscapes (e.g., parks), which are carefully managed, may be used as a controlled environment to test the climate resilience of different species and habitats under different types of management intervention. By contrast, wild land would be more representative of uncontrolled management with a minimum of human intervention. However, many other landscapes would then fall somewhere in the spectrum between these two extremes.

Further investigation of public perceptions is required. Use of 'landscape narratives' may be a useful process to better understand different perception of change to help reveal underlying understandings of nature, climate and human-environment relationships together with how this helps people rationalise different adaptation options (e.g., Köpsel *et al.*, 2017).

#### 3.19.3.1 Indicative costs and benefits of additional adaptation (N18)

This is a very large risk and opportunity, and it is difficult to cover the costs and benefits of adaptation without more detailed and disaggregated analysis. Furthermore, there is very limited published evidence on costs and benefits for this topic. In general terms, enhanced monitoring would be a low-regret option, especially as part of adaptive management. There are an existing set of measures for conservation, landscape restoration, etc. with cost estimates, but it is more difficult to assess the marginal actions needed to address climate change risks.

#### 3.19.3.2 Overall Urgency Scores (N18)

<b>Table 3.64 Urgency Score for risks and opportunities from climate change to landscape character</b>				
	<b>England</b>	<b>Northern Ireland</b>	<b>Scotland</b>	<b>Wales</b>
<b>Urgency score</b>	Further investigation	Further investigation	Further investigation	Further investigation
<b>Confidence</b>	Low	Low	Low	Low/Medium

Some important recent initiatives have demonstrated how adaptation could be integrated with landscape concepts, especially at local level, which has advantages because this is consistent with the landscape scale and can facilitate enhanced public participation. However, evidence is still

limited, and it is difficult to determine effectiveness of proposed adaptation actions against projected future risks. Based upon this assessment, we recommend 'Further investigation' for this topic to encourage policy support, trialling, and continued knowledge exchange to further implement these approaches throughout the UK and for a wide range of different landscapes.

Adaptation actions include the following:

- Further policy support for existing pioneering approaches linking climate-smart adaptation measures with Net Zero planning in the context of national planning frameworks.
- Clearer national-level guidance and objectives for including adaptation in LSCA and other related assessment tools (e.g., for geoheritage).
- Further development of joint research programmes and strategies linking the natural environment and cultural heritage to define and investigate common adaptation outcomes for specific landscape types and locations.
- Further investigation of the role of traditional land management practices with regard to landscape-scale adaptive management for both the natural environment and cultural heritage together.

#### 3.19.4 Looking ahead (N18)

Further development of LSCA concepts is required at multiple scales (national to local) integrating climate change risks and responses (also integrating adaptation with Net Zero planning) and for the future based upon combined climate change and socioeconomic scenarios. Landscape character could also be further linked to other related frameworks in a landscape-scale approach (e.g., ecosystem services and landscape functions; use of 'soilscapes' to integrate soil functions.)

Further research on relationships between changes in landscape character and subjective well-being would also be very useful. For example, research on the relationships between personal well-being and the impact of invasive species on specific landscapes has identified potential differential impacts on some parts of the community (e.g., emerald ash borer in USA: Jones, 2017).

### 3.20 Cross-cutting Risks (including with other CCRA Chapters)

The risks and opportunities in this chapter have been assessed individually as per the CCRA method, but, as has been noted throughout this chapter, there are a number of factors that affect them and there are many inter-connections between them and risks in other chapters, as well as between policies promoting adaptation and those supporting other agendas including Net Zero. This final section concludes with a consideration of two examples of these: (i) the synergies and trade-offs between adaptation and the Net Zero policy agenda and (ii) the inter-relationships between the risks and opportunities in the natural environment and the services they deliver, as well as with risks and

opportunities in other chapters. They illustrate the benefits of a more systems-based approach, both to the assessment of the risks and opportunities, and to approaches to adaptation in both policy and practice.

### 3.20.1 Synergies and trade-offs between Net Zero and adaptation for the natural environment

Synergies and trade-offs between climate change mitigation and adaptation actions or policies have been investigated (e.g., Berry *et al.*, 2014; Locatelli *et al.*, 2015; Di Gregorio *et al.*, 2017), but less research has been carried out in the context of the Net Zero agenda. A broad range of interactions with Net Zero have been identified for each risk and for some mitigation options suggested for contributing to achieving Net Zero; their key synergies and trade-offs with adaptation are shown in Table 3.65.

<b>Table 3.65</b> Key synergies and trade-offs identified between mitigation and adaptation, including how Net Zero options influence climate adaptation for the natural environment, and how mitigation options are potentially affected by climate change risks and hence require adaptation.				
<b>Mitigation option</b>	<b>Context dependency</b>	<b>Climate risks to effectiveness of mitigation measure</b>	<b>Synergies with adaptation</b>	<b>Trade-offs with adaptation</b>
Woodland and tree planting	Species used; location	Higher temperatures; loss of cold spells; winter waterlogging; drought; wildfire  Pests, pathogens and invasive species	Increased / improved habitat;  climate adapted species;  enhanced landscape connectivity for species migration;  improved water quality;  reduced flood risk;  soil regulation and health	Monocultures and non-natives could fragment native habitats, increase the introduction and/or likelihood of pests, pathogens and INNS (with possible implications for achieving NZ)
Peatland restoration	Location (upland /	Higher temperatures;	Increased / improved habitat;	Possible decreased short-term water supply

	lowland), restoration method	increased seasonal aridity;  increased rainfall intensity;  wildfire	improved water quality;  enhanced landscape connectivity for species migration;  reduced flood risk; reduced wildfire risk	
Bioenergy crops	Crop type / location;  land use replaced	Soil moisture deficits;  water scarcity;  pests and pathogens	Mixed effects on soils	Possible loss of habitats for wildlife;  decreased water quality;  possible loss of land for food production
Low carbon farming (including CH <sub>4</sub> and N <sub>2</sub> O reductions)	Land capability grade / class	Temperature;  precipitation;  humidity;  soil moisture;  CO <sub>2</sub>	Enhanced soil quality;  improved (soil) biodiversity;  improved water quality and quantity;  improved air quality	Potentially with food production if yields are lower
Restoration of marine / coastal habitats	Habitat type / species	Higher sea temperatures;  salinity/ stratification;  CO <sub>2</sub> -driven acidification;  higher sea levels;  storms	Increased / improved habitat;  enhanced species migration;  coastal protection	

In many cases, because of the multifunctionality of the natural environment and dependency on where and how the Net Zero options are implemented, there are often mixed effects on adaptation and the risks. This was particularly noted for woodland planting and bioenergy, where, for example, monoculture plantations are much more vulnerable to climate extremes, such as drought, windblow, and pests, pathogens and INNS. For all of the options more knowledge is needed on their context dependency and the magnitude of their impacts and interactions. Like nature-based solutions, there can be other co-benefits or trade-offs not captured by this analysis, particularly those relating to human health and well-being resulting from improved or increased habitat area or possible opportunities for enjoyment of the natural environment. There is an opportunity to maximise the mitigation-adaptation synergies, and minimise the trade-offs, thus turning the mitigation options into nature-based solutions. The co-benefits from nature-based solutions link to ecosystem services (3.20.2) and to risks in other chapters, such as those relating to water, flooding and food security.

Also considered in this chapter, but currently not part of the Net Zero budgets are the contribution of coastal and marine habitats to climate mitigation. Both sequester “blue” carbon but are susceptible to the impacts of climate change (e.g., from coastal squeeze or ocean acidification – see Risks N14 and N17). There are also potential implications through increased development of coastal and offshore renewable energy resources as part of a Net Zero scenario.

### 3.20.2 Ecosystem Services and the Role of Nature-based Solutions

The natural environment, in addition to its intrinsic value, provides many critical benefits to people and their well-being. In this final section we further highlight implications and interdependencies by synthesising evidence in terms of natural assets and the ecosystem services they provide (also known as ‘nature’s contribution to people’). In doing so, we also reframe the evidence from the individual risks presented above in terms of the implications not only for this chapter but for other CCRA chapters. This perspective aims to focus on key ecosystem services delivered from respective natural assets (recognising that there are many other connections that can exist and that they may be conceptualised in different ways) and to identify not only risks but also the scope and current progress for integrating ecosystem-based approaches into effective climate change responses. Ecosystem-based adaptation and nature-based solutions both aim to recognise and work with (rather than against) the natural resilience and adaptability of the natural environment.

When reframing risks in this format we also aim to highlight important inter-relationships between the ecosystem systems themselves, in addition to goods and benefits provided to people (Figure 3.18). Typically, it is the relationship of the ‘final service’ with people that is most strongly recognised, especially key provisioning services such as food, fibre, and water supply. In addition, especially at a local level, people have diverse cultural interactions with the natural environment that provide less-quantifiable, intangible benefits, such as through sense of place, identity, and amenity value. However, from the perspective of this chapter, we especially aim to recognise and emphasise that the stability and resilience of ecosystems is maintained by a complex array of natural processes, feedbacks, and functions that provide key regulating ecosystem services. These latter services include benefits from hazard risk alleviation (flooding, erosion etc.), but also the functioning natural systems that are integral to our notions of a safe and healthy environment as represented by

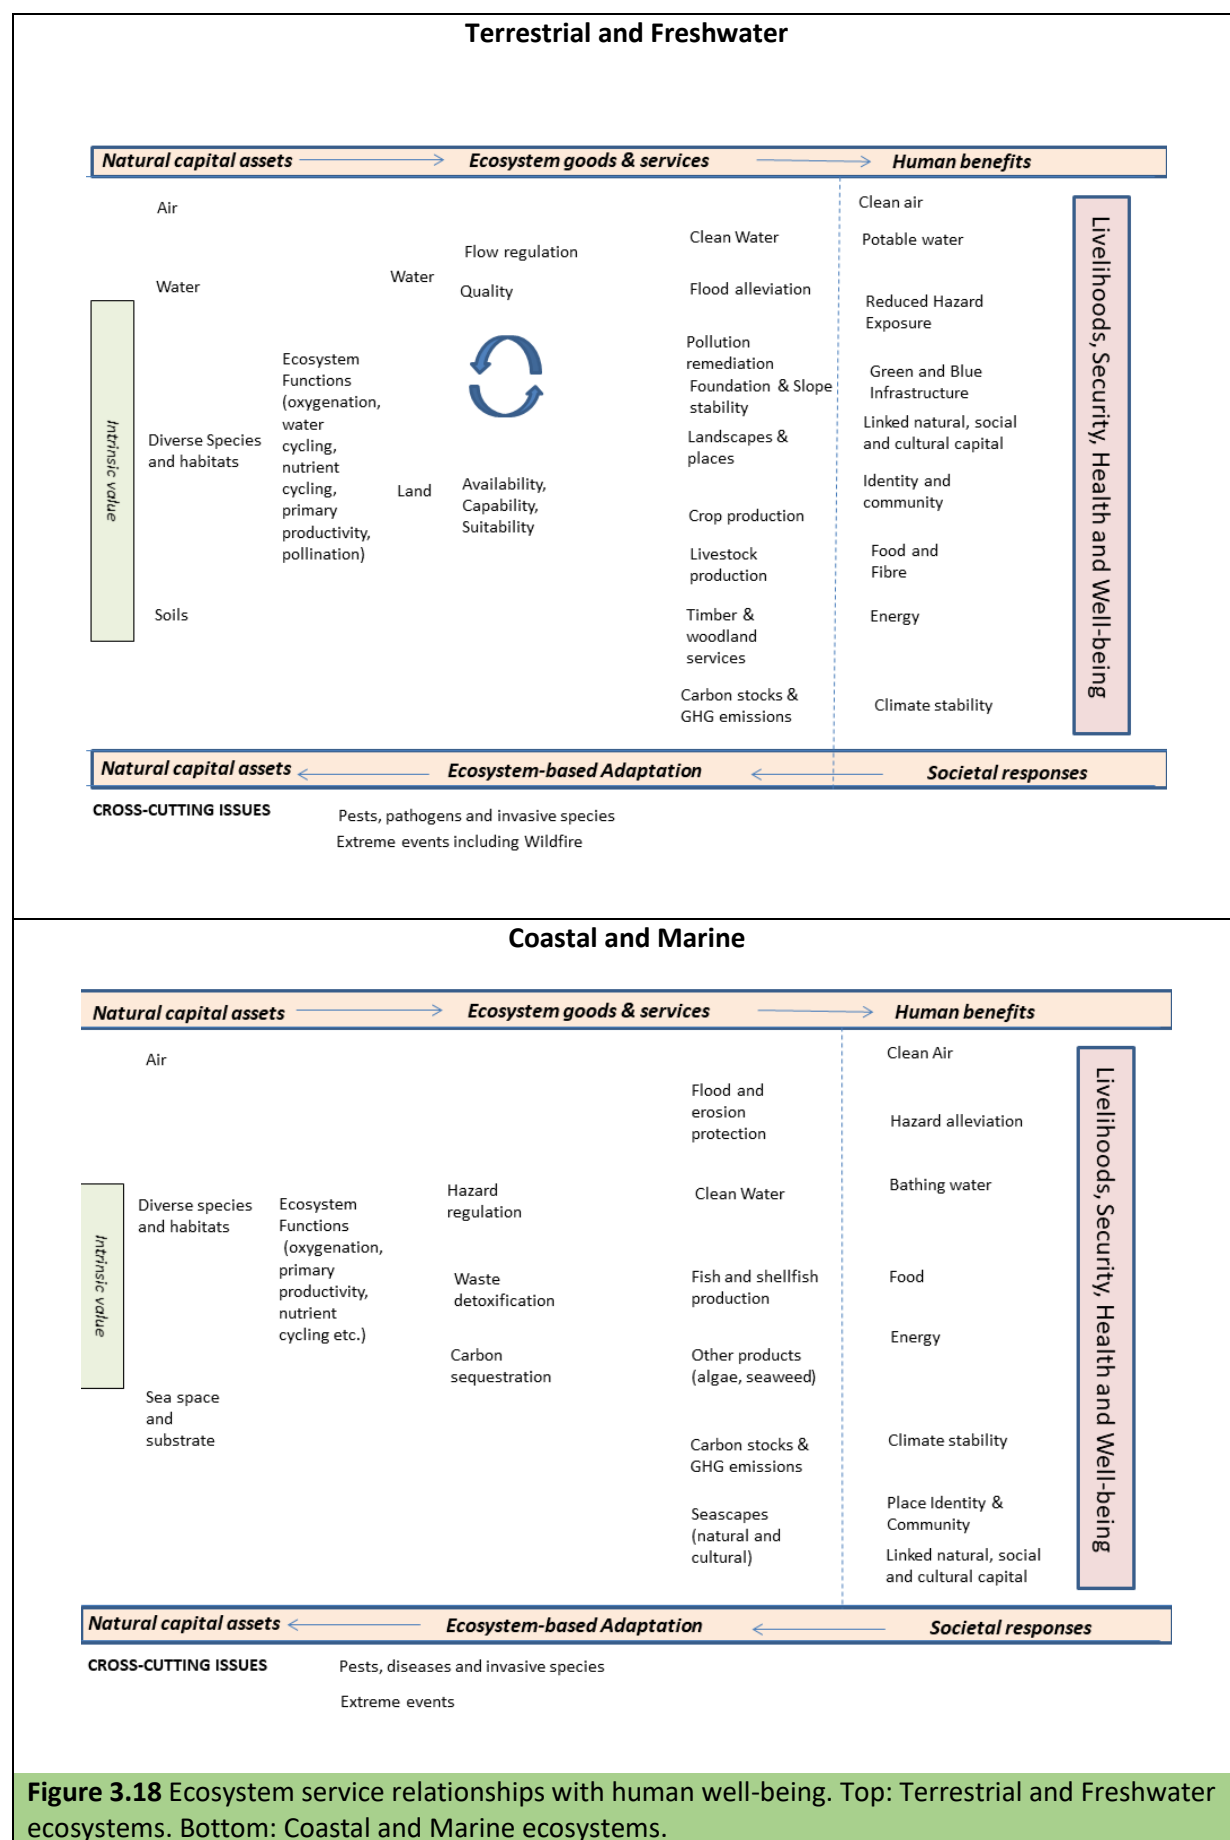

soil quality, water quality, land quality, air quality, or an equable climate, as recognised in international accords, national policy commitments, and societal expectations.

Collectively, these many diverse and interconnected components of the natural environment that contribute to our quality of life can be recognised as Natural Capital. Such terminology can provide a useful analogy to other essential forms of ‘capital’, although as already outlined with unique and sometimes less tangible attributes that challenge attempts at generalisation and simplification (see Dasgupta, 2021). In practice, therefore, the summary findings presented here will require further contextualisation, as, for example, through key ecosystem service relationships both in and between upland and lowland environments, or for urban and rural contexts, or in the context of the coastal zone and the marine environment.

For climate change, one of the primary reasons for concern regarding ecosystem services is the existence of thresholds and even tipping points beyond which ecosystem reorganisation occurs, modifying their functions and services. As we have already highlighted for the 18 individual risk descriptors above, climate can be a key risk factor in crossing these thresholds, and likelihood of threshold exceedance becomes much more pronounced at a 4°C compared to a 2°C world. In reality, risk thresholds may be even closer to the present-day climate than when considered from just a climate driver perspective, as climate change is interacting with other severe environmental co-stressors that reduce overall resilience (e.g., pollution; soil degradation; biodiversity loss).

Although the risks to ecosystem services and hence benefits of more effective risk management may be defined here primarily in terms of a one-way relationship between the natural environment and the other CCRA chapters, we also recognise that for effective adaptation to occur a two-way relationship must be identified and managed. Therefore, effective adaptation in the natural environment is crucially inter-dependent on recognition by other sectors of the mutual benefits from healthy, functioning ecosystems and biodiversity, and for this to be explicitly incorporated into a more joined-up cross-sectoral approach to adaptation responses. This includes requirements for an improved shared understanding of objectives for a sustainable future in the context of a healthy natural environment, cultural heritage, communities, livelihoods, and business functions. Furthermore, emphasis here is placed on UK relationships, but it should be noted that an overly narrow perspective also runs the risk of displacing and degrading natural capital and ecosystem services in other countries. Conversely, if the international flow of goods and services is disrupted (see Chapter 7: Challinor and Benton, 2021), this may place greater pressure on UK natural assets and ecosystem services.

Although ecosystem service relationships are increasingly recognised, there are still many notable gaps in policy implementation in a climate change context. For example, wildfire risk assessments do not yet fully incorporate the importance of protecting natural capital stocks (Belcher *et al.*, 2021) and evaluation of flood risk management plans in Cumbria has noted a lack of inclusion of key ecosystem service relationships in the plans (Huq and Stubbings, 2015). The fundamental importance of understanding and addressing these cross-cutting relationships for developing a more joined-up approach to climate change risk management therefore identifies that they should be a very high priority in forward agendas. This is applicable both in terms of combined government cross-departmental policy action but also in terms of knowledge development and exchange through funded research programmes that are consistent with the scale of the challenge.

### 3.20.3 Implications for Key Ecosystem Service Relationships

Based upon the principles identified above, a series of key ecosystem services relationships (ESRs) can be highlighted for which climate change has important cross-cutting relationships across multiple CCRA risks (as labelled by Chapter identifier).

#### 3.20.3.1 Soil Integrity including Slope Stability (ESR 1)

As assessed for Risk N4, many soils in the UK are in a degraded state and at further increased risk from climate change. This is of major concern because of the fundamental role of soils in the functioning of terrestrial ecosystem systems, in combination with above-ground biodiversity (Risk N1). Soil health is therefore crucial for a broad suite of ecosystem services, including soil fertility for food and fibre production (ESR 5), organic matter for carbon storage (ESR 6), and soil infiltration/filtration processes in naturally regulating water quality (ESR 2) and water flows (ESR 2 and 3). These benefits also extend to the urban environment, including for Sustainable Drainage Systems (SuDS) (ESR 3 and 7). Issues affecting soil structure and slope stability can also have direct negative effects on Infrastructure (Risks I5 and I7) that may be alleviated by enhanced use of the binding properties of plant roots and organic matter. As also noted for Risk N4, increased rainfall intensities from climate change present particular risks for re-mobilisation of spoil heaps and toxic material in contaminated land, and an enhanced role for phytoremediation may therefore have significant benefits for risk reduction.

#### 3.20.3.2 Water Purification and Regulation (ESR 2)

As covered by both Risk N4 and Risk N11, which collectively cover soil-water interactions, climate change is increasing threats to water quality from toxic materials (including pesticides from agriculture), excess nutrients (N and P), and sediments including DOC. These have implications both for drinking water quality (including challenges for treatment plants, notably disinfection by-products such as THCs from DOC) and for bathing water quality (rivers, lakes, and sea, including harmful algal blooms from excess nutrients). The benefits from addressing these risks through nature-based solutions (including improved land management) that enhance raw water quality as a public good is therefore a key ecosystem service that can directly address human health issues highlighted in Chapter 5, Risk H10 (Kovats and Brisley, 2021). In addition, soil-water-vegetation interactions have a key role in regulating water flows which, in addition to the benefits from natural water retention for food/fibre production (ESR 5), can help maintain water supplies (public or private) during drought. The latter also has a related indirect benefit in helping to offset problems that occur during very low flows when dilution of pollutants is further reduced and safe concentration levels for human health exceeded (Risks I6, I8, H10, H11, and B5). Furthermore, natural flow regulation is also of key importance for moderating high flows through flood alleviation benefits (ESR 3) and for Sustainable Drainage Systems (SuDS) (ESR 3 and 7).

#### 3.20.3.3 Fluvial/Pluvial Flood Hazard Alleviation (ESR 3)

Soil-vegetation interactions also modify rainfall-runoff interactions. Therefore, during high flow events, natural soil and vegetation processes and active geomorphological processes can reduce the

speed and quantity of water reaching streams and rivers. This can act to moderate peak flow magnitudes and in turn reduce flood risk. In addition, infiltration processes in healthy soils can reduce surface water flooding in vulnerable topographic locations. Recent increases in severe flood events and the prospects for further increased flood risk from increased precipitation rates in climate change projections (see Chapter 1: Slingo, 2021) has meant that there is a greater interest in using natural flood management (NFM) schemes to help alleviate flood risk. This has been emphasised by indications from recent severe flood events that conventional deterministic and structural approaches to flood prediction and protection have inherent limitations in a non-stationary climate (e.g., Spencer *et al.*, 2018). NFM approaches could have important adaptation benefits for infrastructure, people and the built environment, agricultural land, and businesses (Risks N6, I2, I4, H3, B1, B2: see also Sayers *et al.*, 2020), especially when scaled-up from initial small-scale schemes to catchment scale. However, most of the fluvial environment in the UK is not in a natural functioning state: analysis in England has shown that only 0.5% of the notional fluvial floodplain (as defined by Environment Agency risk maps) is now functional wetland (ca. 3000 ha) (Entwhistle *et al.*, 2019). The same analysis has shown that intensive agriculture on this floodplain zone has increased from around 38% in 1990 to 62% in 2007, although it has since remained relatively static (64%) to 2015 with indications of some arable areas being transformed to pasture.

Increased adoption of NFM requires improved awareness of the need to address existing scientific, institutional and political barriers to its implementation. To date, most of the assessments of NFM have come from small-scale schemes (e.g., ‘leaky dams’) that aim to ‘slow the flow’. The scale effects inherent in ecohydrological processes means these cannot simply be extrapolated to medium or large-scale catchments. In addition, modelling of land use change (e.g., by afforestation) at catchment scale has been used to investigate larger-scale responses. Such modelling again shows considerable benefits from NFM, although it is probable that the largest extreme rainfall events will still result in severe flooding. There has been rather less research on ‘room for the river’ type schemes that aim to create more natural flood storage outwith high risk areas by re-connecting rivers with their floodplains, although some work from other countries indicates considerable benefits from such large-scale approaches if the institutional issues can be overcome (e.g., Molenveld and van Buuren, 2019).

A key issue to recognise for fully-functional NFM schemes (e.g., ‘room for the river’ schemes; wetland creation/restoration; restored floodplain connectivity; riparian/upland woodland) is that they cannot be assessed with the same conventional engineering approaches used for structural defences, such as by inferring a fixed standard-of-service level of protection. Natural systems are inherently adaptable and will naturally adjust from one extreme event to the next (in addition to during more normal periods). In some cases, small-scale hybrid NFM schemes have been developed (e.g., flood retention ponds and bunds) that are both engineered and allow some form of ‘natural’ processes, but adoption of fixed design criteria can remove natural adaptability following each event, especially in the context of the wider catchment response. Therefore, in some catchments a more realistic solution may be a combination of natural and hybrid or structural approaches in order to protect high-risk locations but also retain natural resilience and adaptability. Especially in urban settings, climate change modifications to rainfall frequencies and magnitudes highlight further advantages from natural processes through Sustainable Drainage Systems (SuDS) (see Risk I3 and ESR 7). In all cases, however, the key step for effective adaptation will be to consider rainfall-runoff responses at catchment level and to use integrated catchment management to develop

complementary, proactive approaches, rather than to employ piecemeal, reactive approaches after extreme flood events.

#### 3.20.3.4 Coastal Flood and Erosion Hazard Alleviation (ESR 4)

In Risk N17 we have highlighted the importance of considering erosion and flood risk together from a natural environment perspective, due to them being inter-related processes, but this also has implications for the role of coastal habitats in alleviating flood and erosion risk for infrastructure, people and property, and businesses (Risks I3, H4, B1, B2), especially in hotspot locations (Narayan *et al.*, 2016; Christie *et al.*, 2017). As also noted in Risk N17, in many locations the natural flood and erosion protection is being degraded by coastal squeeze; this is then increasing the threat for interdependent risks in other sectors as they become more reliant on structural interventions that are not practical or cost-effective to maintain, especially with the increased likelihood of higher water levels from sea-level rise (e.g., Cooper *et al.*, 2016; Brown *et al.*, 2017). Shoreline Management Plans are intended to recognise these key interdependencies, and, especially as they are defined based upon natural units defined by coastal cells, to recognise the key role of sediment supply in a sustainable coastline. SMPs include the possibility to define managed realignment or no active intervention for a segment of coast, but as also noted for Risk N17, political and public pressures often act against this happening, undermining the original strategic purpose of SMPs. However, there are some positive examples of a more proactive approach, both at SMP level and also through specific organisations or partnerships that recognise the advantages of working with natural processes in the short-term and longer-term. Similar issues also arise for the further development of NFM approaches on the coast as discussed above in a fluvial context (ESR 3), including the need for an integrated approach throughout the defined coastal cell unit, and where necessary in combination with hybrid schemes or hard engineering structures.

#### 3.20.3.5 Food and Fibre (ESR 5)

Implications of climate change for the food- and fibre-related outputs from agricultural and forestry systems are assessed in Risks N6 and N9 based upon the raw products. In addition to agriculture and forestry businesses, impacts on these farmgate or forest outputs (which have key dependencies with soil and water quality, and biodiversity, such as through pollination) also have implications for businesses in the supply chain that process and distribute food and fibre (Risks B6 and B7), and for food safety (Risk H9). There may also be opportunities here for health and for businesses from enhanced provision of local food, especially where its quality can be assured through environmental quality (Risks H7 and B7). Implications for fisheries (both capture fisheries and aquaculture) are assessed in Risks N14 and N15, and these also have critical links with the health of the wider marine environment, as recognised by increased interest in applying an ecosystem-based approach to fisheries management. Again, the continued sustainability and quality of marine produce is of high importance for suppliers and processors, and for associated coastal communities.

#### 3.20.3.6 Carbon Storage (ESR 6)

Both risks and opportunities for carbon storage are addressed in Risk N5. This is obviously an ecosystem service with global-scale benefits in addition to contributing towards the UK Net Zero commitment. This Chapter further highlights the importance of understanding carbon storage capabilities across all environments and land uses, including coastal and marine systems through

‘blue carbon’. However, Risk N5 also identifies limited progress on assessing the resilience of this key ecosystem service in the context of ongoing climate change, including any planning assumptions for a 2°C or 4°C world. There are many direct and indirect links here with climate change risks, but with increased emphasis on the Net Zero agenda and on climate-related risk disclosure for businesses (Risk B4), interaction of ongoing climate change with plans for validated and verified decarbonisation using ‘natural solutions’ should be especially prominent.

### 3.20.3.7 Green and Blue Infrastructure (GBI) (ESR 7)

For this relationship, we recognise multiple ecosystem services that occur through the presence of greenspace and bluespace (i.e., water features), notably in combination as part of a coherent network of interlinked habitats, and more especially to integrate the benefits of the natural environment for people within urban areas. These multiple benefits include: the natural cooling effect of GBI (through evapotranspiration etc.) compared to built infrastructure, which can have an important role in reducing Urban Heat Island (UHI) effects, and therefore heat stress health issues during heatwaves (Risks H1 and B5); water quantity/quality benefits (ESR 2 and 3); reducing negative air quality issues for human health (Risk H7); and the amenity value or broader cultural and health benefits (ESR 8 and Risk H2) from access to GBI (Doick *et al.*, 2014; Edmondson *et al.*, 2016; Gunawardena *et al.*, 2017; Smithers *et al.*, 2018; Brown and Mijic, 2019). Assessments of these benefits are now being provided for use in integrated planning; for example, average alleviation of UHI effects when aggregated for 11 UK city regions was estimated at between -0.63°C and -0.88°C (depending on land cover type), whilst overall value of urban GBI in these 11 city regions was found to be £166 million annually (Office for National Statistics, 2018). There are also important linkages with the Net Zero agenda including measures to enhance carbon storage and reduce GHGs (Risk N5 and ESR 6). In an adaptation context, there are likely to be considerable added benefits from integrating GBI with other related initiatives in the urban environment (Emmanuel and Loconsole, 2015), notably Sustainable Drainage System (SuDS) schemes. These aim to improve management of surface water drainage through increased use of natural processes, addressing both water quantity (flooding) and water quality (pollution) risks whilst enhancing biodiversity and amenity benefits, especially in the context of local landscapes (Risk N18). This will require that GBI is more fully integrated with conventional approaches to infrastructure and plans to make it more climate-resilient (see Chapter 4: Jaroszowski, Wood and Chapman, 2021).

### 3.20.3.8 Cultural Interactions (ESR 8)

The natural environment is a source for many forms of cultural interaction that contribute to human wellbeing including through inspiration, recreation, recuperation, and identity (Capaldi *et al.*, 2015). In this CCRA chapter we have especially highlighted this relationship through the role of landscapes (and seascapes) and sense of place (risk N18), recognising also the important interaction with cultural heritage (Risk H12). These interactions are complex and typically intangible, meaning they are easily overlooked in a quest for metrics that facilitate easy quantification, but are particularly important at local and regional level (Tschakert *et al.*, 2019). As explained further in Chapter 5 (Kovats and Brisley, 2021), there can be important psychological impacts associated with this relationship, including on mental health and social cohesion across different societal groups and generations, that require further investigation, but also require increased awareness in decision-making (Chiabai *et al.*, 2018). These interactions include both rural and urban areas, as for example

with local landscapes or local food initiatives (e.g., allotments, diverse food crops and ethnic communities; Kell *et al.*, 2018)

### 3.20.3.9 Natural Control of Pests, Pathogens, and INNS (ESR 9)

A narrow utilitarian perspective would consider this issue as primarily defined in terms of an ecosystem 'dis-service' but this misses the importance of the broader issues with regard to the natural environment. In a healthy and fully functioning system, the wide diversity of biotic and abiotic interactions tends to mean that it is difficult for a species that has a detrimental effect for humans to rapidly establish and spread. Biodiversity, therefore, has a key role in controlling spread of pests, pathogens and INNS, and this role extends to having important implications for human health (Risk H8). CCRA1 discussed this 'biodiversity dilution effect' as a working hypothesis and since that time, more evidence has been presented to support the proposition, although more research is also required. Much of the evidence from both a UK and a global perspective is in reality negative, showing that if natural habitats are fragmented by humans and biodiversity is lost, then the spread of pests, pathogens, and INNS becomes more prevalent (as summarised by the recent IPBES (2020) report on pandemic risk). The current Covid-19 pandemic, which evidence suggests originated from zoonotic interactions (as with previous outbreaks such as SARS, MERS, Ebola, avian influenza and swine flu), has only further highlighted the importance of this issue and the role of the natural environment in zoonotic epidemiology (see case study on Covid-19 in Chapter 7: Challinor and Benton, 2021). A particularly important approach that can advance this ecosystem service relationship is Integrated Pest Management: promoting use of more sustainable biological controls to pests and pathogen vectors as an alternative to excessive use of chemical controls that can have an array of long-lasting negative side effects on both the natural environment and human health. This can also include use of research to identify pest and disease resistance in wild ancestors of present-day agricultural, horticultural or forestry varieties, which may be then applied to the susceptible commercial varieties. In addition, further attention to landscape configuration to diagnose existing problems and enhance diversity at multiple levels (from genetic and species level to habitat mosaics) can also act to further enhance natural control measures ('landscape epidemiology' in Plantagenest *et al.*, 2007).

### 3.20.4 Progress on Adaptation for Key Ecosystem Service Relationships

The benefits from ecosystem services and NBS are increasingly recognised in policy frameworks as shown by the 25YEP in England, the Sustainable Land Strategy in Northern Ireland, the second Scottish Climate Change Adaptation Programme (SCCAP2, which uses an ecosystem services framework in defining target outcomes) and the Land Use Strategy in Scotland, and the Future Wales National Development Framework and spatial plan. However, as highlighted above for key ecosystem services relationships, progress on implementation with regard to ecosystem-based adaptation and nature-based solutions remains limited, and often based upon specific case examples, rather than becoming a central and integral component of the adaptation solution space. A key challenge remains in matching prospective solutions to their context, especially for maximising synergies through multiple benefits, and in recognising that natural systems are dynamic and naturally adapt to change (especially based upon their inherent climate sensitivity). This necessitates

a flexible rather than a prescriptive approach and the need for improved regular monitoring to better understand how natural and human systems adapt together.

We conclude by noting the following cross-cutting issues for adaptation of ecosystem services that will be crucial in developing a more coherent relationship between the natural environment and other sectors as the climate continues to change, and to ensure that trade-offs between individual risks are minimised and that synergies are maximised:

- (i) The relationship of ecosystem services with natural processes means they do not usually neatly follow administrative boundaries, requiring a coordinated approach to adaptive management (including both urban and rural authorities). Prominent examples include river catchments and coastal cells for Shoreline Management Plans. The need for improved and integrated planning linking land and sea has also been emphasised by the recent Defra Marine Pioneer project (MMO, 2021).
- (ii) The inter-relationships between ecosystem services requires a cross-cutting approach to avoid overemphasis on addressing risk or opportunities for one service or service type at the expense of others (especially those that may be less tangible or easily quantifiable, such as cultural interactions).
- (iii) More emphasis and research initiatives are required on key thresholds for ecosystem services in the context of climate change, especially regulating services through providing the key link with natural processes, and their implications for safe regulatory limits (water quality, soil quality etc.). Furthermore, the existence of thresholds, feedbacks and other non-linear responses, including from cumulative impacts, means that prediction of future change is inevitably constrained for the natural environment and adaptation responses will need to appropriately recognise this (e.g., through multiple adaptation pathways).
- (iv) The interaction of ecosystem services with both climate change AND socio-economic drivers (e.g., demographics; social attitudes) will be crucial and requires better integration into planning frameworks to help ensure plans are robust and sustainable.
- (v) Caution needs to be applied in applying simple indicators for progress monitoring on ecosystem services that neglect important spatial and temporal variations in the relationship with natural processes (including contextual factors such as land use change and local climates etc.). There are therefore inherent challenges in using simple metrics such as 'area restored', because the outcome may be very variable for different locations. Similarly, concepts of 'no net loss' based on just areal measures do not provide an adequate measure of ecological or hydrological coherence or function. As a precaution against the inevitable uncertainties involved with natural processes and climate change adaptation, measures should really be seeking a considerable 'net gain' at present as an insurance measure to enhance resilience against future uncertainty.
- (vi) Climate change is increasingly going to require permanent change, and hence the management of change is also becoming an increasing component of the required response to address risk and realise opportunities. This transition management will also require a cross-

sectoral approach across multiple ecosystem services, as for example linked to agreed shared outcomes as now being envisioned by long-term policies such as the 25 Year Environment Plan for England, Land Use Strategy for Scotland, Future Wales National Development Framework and spatial plan, or Northern Ireland Sustainable Land Strategy. In this context, it can also be highlighted that the Natural Capital Committee have consistently recommended to the UK Government that natural capital should be viewed as a key component of UK infrastructure. In addition, a report by the National Infrastructure Commission (NIC, 2021) stressed that infrastructure can play a key role in making a positive contribution to the environment, through incorporating a natural capital perspective into infrastructure projects, and to achieve environmental net-gain.

- (vii) In addition to modifying the magnitude of risks, climate change also increases uncertainties. This highlights additional advantages that may be gained from diversification as a generic option for adaptive risk management. From a land use perspective, this implies measures to promote intentional addition of functional biodiversity at multiple spatial and temporal scales in the landscape. In agriculture, increased evidence of diversification approaches is available (e.g., organic amendments, reduced tillage, crop diversification) across a range of ecosystem services whilst not compromising yield (Skaalsveen *et al.*, 2019; Tamburini *et al.*, 2020; Cooper *et al.*, 2021). A similar picture is evident for adaptation in forestry, from genetic to species to landscape-level diversification (Forestry Commission, 2020b).
- (viii) There are very important relationships between ecosystem services and societal inequalities, including in some cases either increased reliance on a healthy natural environment, or difficulties in accessing the benefits from the natural environment. These require further prioritised attention, as without further progress on improving this issue, the additional effects of climate change may lead to exacerbated inequalities. The recent Dasgupta (2021) economic review of the links between natural capital, sustainability and inequality (commissioned by HM Treasury) have further highlighted the need for a fundamental reappraisal and prioritisation of these relationships.
- (ix) A key issue emphasised throughout this chapter, both for assessing changes in risk magnitude and adaptation progress in moderating risk, is the need for improved strategic frameworks for monitoring and evaluation, including to share improved information on responses in the context of 'what works, where, and when'. This requires improved collaboration between academics, practitioners, and policymakers, supported by appropriate funding.

4.15 Case Study - Toddbrook Reservoir	191
4.16. References	193

## Key Messages

- **Flooding remains a key risk to infrastructure with the latest climate projections indicating an increased likelihood of heavy precipitation.** There have been a large number of recent high-profile events (e.g. the floods of East Yorkshire in 2020, the Toddbrook Reservoir incident in 2019) which highlight, with increasing confidence, the high magnitude of such risks and their interacting risks and consequences (sections 4.2.1 and 4.3.1). There has been some limited progress across the infrastructure sector in both assessing and adapting to the risk via a suite of flood protection measures (section 4.3.2). However, increasing winter rains will ensure the risk needs sustained management, as will coastal flooding. Revised projections indicate a sustained rise in mean sea levels around the UK (section 4.4.1). The latter is one area in which adaptation pathways are being used extensively (e.g. management of flood risk in the Thames Estuary) and other shoreline management plans (section 4.4.2).
- **Water scarcity in summer remains a concern for supply.** Without adaptation and under a central population growth scenario, the water deficit across the UK by the late 21<sup>st</sup> Century is projected to be approximately 1220 and 2900 Ml/day for pathways to 2°C and 4°C global warming respectively. This equates to the daily water usage of around 8.3 to 19.7 million people (HR Wallingford, 2020. See section 4.9.1). This increase in risk is a combination of population growth and climate change.

To maintain the current levels of risk (to the worst historic drought) in the face of rising population, environmental and climate pressures by the 2050s, would require additional capacity of about 2,700-3,000 Ml/day in England. Further adaptation is likely to be needed; this will more likely be measures that actually reduce demand rather than improve supply (section 4.9.3). Actions to increase supply are also being explored.

- **While significant progress has been made, an adaptation shortfall appears to remain for storms, lightning and high winds in the energy sector.** An increasing dependency on the electricity network (section 4.2.1) means that energy supplies will need to become increasingly resilient to a range of increasing weather and climate risks across the sector (section 4.11.1). In particular, there is an adaptation shortfall to the effects of storms, lightning and high winds (linked to impacts on vegetation), although adaptation to heat and flooding is developing well. Water scarcity will also impact on the energy sector by limiting the cooling of thermal power plants (section 4.10.1) along with uncertain implications for hydroelectric generation (section 4.7.1). There are also considerable uncertainties regarding the effects of the changing future energy mix in the UK in line with Net Zero strategy (e.g. water requirements for the portfolio of Net Zero supply options). In particular, a notable further risk to energy generation is from an increasing reliance on generation of energy from offshore wind which is exposed to storms and high waves (section 4.12.1), although the exact impact of climate change on these phenomena remains uncertain.

- **A changing climate continues to be a problem for the transport sector.** Both Network Rail and national highways agencies have been proactive in implementing adaptation measures on national networks, but sustained action is still required. Significant risks are still posed to railways with respect to flooding (sections 4.3.1 & 4.4.1) and heat (section 4.13.1). On roads, problems are more likely to occur on local roads and smaller schemes (section 4.13.3) and indeed, there is an underlying need to assess the impact of single points of failure more broadly (e.g. bridges (section 4.5.1), earthworks (section 4.6.1) and subsidence (section 4.8.1)). Often a paucity of data is restricting progress in these areas.
- **The systems nature of infrastructure means that any unmitigated risk has the potential to have a propagating impact across the network or lead to cascading failures across multiple networks.** The consequences of cascading risks cause far-reaching social and economic disruption beyond the initial impact. Extensive research is still required into cascading and interacting risks with high profile case studies (e.g. flooding at Stansted Airport in 2013, the impacts of Storm Desmond in Lancaster in 2015) providing increasingly high confidence in the significant magnitude of the impacts (section 4.2.1). This is set to increase with climate change as the individual costs associated with impacts on each network become compounded. The increasing reliance on electricity (section 4.2.2) and Information and Communications Technology (ICT) (section 4.14.1) both represent key areas needing attention. For the latter, there remains a lack of publicly available information to ascertain the true scale of any vulnerabilities in the sector (section 4.14.2).
- **Current national planning policies for infrastructure differ in the extent to which climate impacts and adaptation are addressed.** For new major infrastructure the 2017 update to EIA regulations in England, Scotland, Wales and Northern Ireland, includes a requirement to assess the infrastructure's vulnerability to climate change, however it is not clear how comprehensive these assessments are in practice. Flood risks are also considered at the planning stage. There are fewer requirements for existing infrastructure to adapt to climate change. Some sectors have well-developed plans while other sectors are less well organised or have no coordinating body. Overall, there is a need for a coordinated, cross sectoral review of design codes and standards, climate risk guidance, inspections and maintenance guidance, and wider relevant industry guidance on risk management to incorporate the latest understanding of climate impacts.

Table 4.1 summarises the urgency scores for the 13 risks to UK infrastructure from climate change, using the urgency scoring system described in Chapter 2 (Watkiss and Betts, 2021). The CCRA3 list of risks and opportunities, developed in consultation with stakeholders, did not include any opportunities for UK infrastructure from climate change.

**Table 4.1:** Urgency scores for risks to Infrastructure

Risk number	Risk description	Urgency scores			
		England	Northern Ireland	Scotland	Wales
I1	Risks to infrastructure networks (water, energy, transport, ICT) from cascading failures	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)
I2	Risks to infrastructure services from river and surface water flooding	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)
I3	Risks to infrastructure services from coastal flooding and erosion	Further investigation (Medium confidence)	Further investigation (Medium confidence)	Further investigation (Medium confidence)	Further investigation (Medium confidence)
I4	Risks to bridges and pipelines from flooding and erosion	Further investigation (Low confidence)	Further investigation (Low confidence)	Further investigation (Low confidence)	Further investigation (Low confidence)
I5	Risks to transport networks from slope and embankment failure	More action needed (Low confidence)	More action needed (Low confidence)	More action needed (Low confidence)	More action needed (Low confidence)
I6	Risks to hydroelectric generation from low or high river flows	Further investigation (Low confidence)	Watching brief (Low confidence)	Further investigation (Low confidence)	Further investigation (Low confidence)
I7	Risks to subterranean and surface infrastructure from subsidence	Further investigation (Low confidence)	Further investigation (Low confidence)	Further investigation (Low confidence)	Further investigation (Low confidence)

I8	Risks to public water supplies from reduced water availability	More action needed (Medium confidence)	Sustain current action (Medium confidence)	Sustain current action (Medium confidence)	Sustain current action (Medium confidence)
I9	Risks to energy generation from reduced water availability	Further investigation (Medium confidence)	Watching brief (Medium confidence)	Watching brief (Medium confidence)	Watching brief (Medium confidence)
I10	Risks to energy from high and low temperatures, high winds and lightning	Further investigation (High confidence)	Further investigation (High confidence)	Further investigation (High confidence)	Further investigation (High confidence)
I11	Risks to offshore infrastructure from storms and high waves	Sustain current action (Medium confidence)	Sustain current action (Medium confidence)	Sustain current action (Medium confidence)	Sustain current action (Medium confidence)
I12	Risks to transport from high and low temperatures, high winds and lightning	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)	More action needed (Medium confidence)
I13	Risks to digital from high and low temperatures, high winds and lightning	Further Investigation (Low confidence)	Further Investigation (Low confidence)	Further Investigation (Low confidence)	Further Investigation (Low confidence)

## 4.1. Introduction

### 4.1.1 Scope of Chapter

This chapter assesses the climate-related risks and opportunities to infrastructure, primarily focussing on the ‘economic grey infrastructure’ that provides services such as heating, lighting, mobility, fresh water and sanitation to society, aligned with the remit of the National Infrastructure Commission (NIC). Green infrastructure is beyond the scope of this chapter but is included where appropriate as an adaptation measure. The chapter builds extensively on the equivalent chapter in the second Climate Change Risk Assessment (Dawson *et al.*, 2016) by using new evidence, including (where possible) the latest generation of climate scenarios, to update our understanding of previously identified climate risks and the role of current and future adaptation in the sector. The

Introduction Chapter to this report outlines the process and role of Government in choosing the list of risks and opportunities that have been considered here and in the other chapters. This list was provided to the authors by the CCRA Project Board (Customer).

Risks to current infrastructure have recently been systematically assessed through the NIC (2020). However, the scope of the NIC report covers all hazards, which meant that the specific impacts of climate were not considered in detail. The focus here is on the key risks to infrastructure previously identified from CCRA2, as well as the potential for the interaction of risks with other sectors. Following CCRA2, the descriptors to focus on have been combined and subsequently reviewed and approved by Central Government. The result is 13 indicators for infrastructure (Table 4.1) which will individually be covered in the chapter.

Our society and economies are heavily reliant on infrastructure to function effectively and it is a priority area of investment by the UK government (see Box 4.1). The *National Infrastructure Plan* underpins the co-ordinated delivery of major infrastructure in the UK (although with application for devolved administrations) but currently pays little consideration to climate change. However, recent developments in this area are significant. £640 billion of gross capital investment in infrastructure before 2024-25 was committed in the 2020 Spending Review with a new *National Infrastructure Strategy*. This follows the publication of the first *National Infrastructure Assessment* in 2018 (NIC, 2018a) which included a number of climate change related recommendations such as national flood resilience standards and a plan to enable the water sector to meet changing supply and demand in 2050. This has subsequently led to the recently published *Resilience Study by the National Infrastructure Commission* (2020).

### Box 4.1: Socio-economic scenarios and infrastructure

Social, cultural and economic trends are highly relevant to the future risks of climate change, and strongly influence future magnitude through changes in exposure and vulnerability (see Chapter 2: Watkiss and Betts, 2021). They will also influence adaptation, including the capacity and resources of individuals, organisations and infrastructure operators to act. Cultural and socio-economic factors can act together as risk multipliers exacerbating the impacts associated with disruptions to infrastructure services caused by climate change, although for some cases, these factors can reduce vulnerability and thus dampen the overall impact.

The CCC commissioned a new consistent set of UK socioeconomic projections from Cambridge Econometrics (Cambridge Econometrics, 2019) as one of the CCRA3 research projects.

These include projections of population growth, population ageing, and migration (internal migration and immigration), presented in Chapter 5 (Kovats and Brisley, 2021). The central scenario assumes that the UK population grows at a steady pace, increasing by over 17 million (compared to 2016), to reach a total population of almost 83 million in 2100. This rising population will likely increase the demand for infrastructure services.

The Cambridge Econometrics (2019) projections provide central, low and high estimates for total GDP (£ millions, real) and percentage growth (from the previous year), based on estimates from the Office for Budget Responsibility (OBR). The Central scenario envisages a GDP annual growth rate for the UK of about 1.6% from 2018 to 2028 and an acceleration with GDP expected to grow by 2.2% per annum from 2029 onwards (through to 2100). The increase in economic growth will also increase infrastructure needs. This means there will be a large increase in the value at risk, in

terms of the infrastructure assets, service levels, etc., which increases the potential exposure to risk (though future economic growth could provide additional resources to address these risks). The socio-economic study also projected gross value added (GVA), employment and labour productivity, all of which are important for the infrastructure needs associated with different sectors. In the Central scenario all sectors experience a similar growth pattern based on the Central GDP growth rates.

There are a very large number of other socio-economic and cultural trends that could have a large influence on demand for services and thus infrastructure. Some of the more important will include the drive towards digitalisation, change to the work environment (noting the shift towards home working from COVID-19), changes in how leisure time is used (particularly regarding travel distances and mode) etc., as well as long-term policy shifts. COVID-19, in particular, has the potential to result in a significant policy change in terms of infrastructure. Although the UK government announced a £640bn investment in infrastructure in the March 2020 budget, additional investment in large infrastructure projects is likely as the UK and the devolved nations seek to rebuild their economies following the pandemic. This will provide opportunities to enhance adaptive capacity in both new and existing infrastructure.

All proposed investments will need to be critically evaluated through a Net Zero lens as the UK government has adopted a Net Zero target through a revision to the 2008 Climate Act (such that the net UK carbon account for the year 2050 is at least 100% lower than the 1990 baseline). The Scottish Government committed to a target of net-zero emissions of all greenhouse gases by 2045 (Scottish Government, 2019a), with the Infrastructure Commission for Scotland placing inclusive net-zero carbon economy at the core of its 30-year vision (Infrastructure Commission for Scotland, 2020). The Welsh Government has announced a 95% reduction in greenhouse gas emissions by 2050 with an ambition to reach Net Zero (Welsh Government, 2019a). This will impact upon the type of infrastructure the UK will be reliant upon in 2050 as well its role within the wider economy and society (see Box 4.2).

#### **Box 4.2: Implications of Net Zero for Infrastructure**

Following the Paris Agreement, the UK and the devolved nations have committed to achieving 'Net Zero'. However, Net Zero is only going to be achieved if clear policies are rapidly put into place to meet the ambitious targets set. Net Zero has implications across all sectors included in this risk assessment as rapid and significant changes will be required. The infrastructure sector is no different and as a significant contributor to UK greenhouse gas emissions, Net Zero will have major implications for the sector. However, at the time of writing, there is no detailed Government policy on how Net Zero will be achieved, and thus there is limited information on what exactly Net Zero will mean for infrastructure. The Climate Change Committee has published a detailed analysis that presents potential pathways to Net Zero for each sector of the economy (CCC, 2019a). It presents scenarios that illustrate the ways in which extensive decarbonisation of the UK economy could occur, by 2050, to demonstrate that a Net Zero emissions target by 2050 is achievable. However, this includes alternative approaches, and the actual pathways to achieve this are still in development and subsequently a long way from actual policy. Regardless of the route taken to achieve Net Zero, there will be implications for the infrastructure considered in this chapter, and interactions (potential positive or negative influences) with many of the climate risks detailed in this chapter. In particular, the anticipated infrastructure transformation in response to

delivering Net Zero goals will encompass significant changes in energy generation and transport, detailed in Box 4.2 Table 1.

**Box 4.2 Table 1:** Potential change associated with Net Zero and implications for UK infrastructure risk

Sector	Risk affected	Examples of changes associated with Net Zero	Implications for UK infrastructure risk
Transport	I1, I2, I5, I12, I13	<ul style="list-style-type: none"> <li>• Electrification of rail and road transport (electric vehicles) including smart charging infrastructure.</li> <li>• Use of alternative fuels. Hydrogen for Rail; low carbon alternatives such as biokerosene for Aviation.</li> <li>• Increased active travel (walking, cycling etc.)</li> <li>• Increased use of public transport.</li> <li>• Increased use of blue infrastructure (e.g., London Blue Ribbon Network)</li> </ul>	<ul style="list-style-type: none"> <li>• Increased reliance on electricity and ICT with associated potential for cascading risks from weather-related damage and disruption to these infrastructures.</li> <li>• New flood risks to new infrastructure (e.g. electric vehicle charge points)</li> <li>• As yet unassessed risks associated with new infrastructure (e.g. hydrogen production, distribution and storage)</li> <li>• Health and safety risks to increased numbers of cyclists and pedestrians from extreme weather.</li> </ul>
Land Use	I2	<ul style="list-style-type: none"> <li>• Afforestation</li> </ul> <p>Changes in farming practices (e.g. low carbon / restoring peatlands)</p>	<ul style="list-style-type: none"> <li>• Potential to reduce infrastructure flood risk management and reduce extreme river flows and their impact on hydropower output (although afforestation is also vulnerable to droughts)</li> <li>• Conversely, flood risk could increase due to</li> </ul>

			increased debris in rivers.
Energy and Water Supply	I1, I3, I8, I9, I10, I11, I13	<ul style="list-style-type: none"> <li>• Doubling or potential quadrupling of low carbon electricity needed to meet demand from other sectors incl. electrolysis (BEIS, 2020a). Rising from ~300 TWh/year in 2017 to 600 TWh/year under the CCC Further Ambition Scenario with potential for further electrification up to 1300 TWh/year (CCC, 2019a, Figure 2.3)</li> <li>• Increased use of renewables: wind, solar, bioenergy with carbon capture and storage (BECCS)</li> <li>• Development of a hydrogen industry.</li> <li>• Increased development of bioenergy supply chains.</li> <li>• Smarter control systems to improve efficiencies.</li> <li>• Reductions in the demand for fossil fuels.</li> <li>• Changes in water demand due to a changing energy mix.</li> </ul>	<ul style="list-style-type: none"> <li>• Increased reliance upon electricity supply increases the consequences of power outages.</li> <li>• Uncertain projections for future wind generation.</li> <li>• Increased significance of loss of offshore infrastructure to electricity supply.</li> <li>• Increased requirements for water for Carbon Capture and Storage (CCS) and hydrogen (H<sub>2</sub>) production increases vulnerability to water restrictions or coastal erosion and sea level rise if they are sited on the coast.</li> <li>• Bioenergy crops can be impacted by drought, resulting in undersupply.</li> <li>• Changes in the spatial distribution of supply to accommodate greater renewable generation.</li> <li>• Increased dependencies (e.g. on ICT) makes cascade failures to other networks more probable.</li> <li>• Changes in water quantity and distribution needs to accommodate a changing energy mix.</li> </ul>

Overall, Net Zero will change the profile of risk. It will underpin the types of new infrastructure to be built, how and to what extent existing infrastructure is used in the future, decisions on adaptation solutions, and offer opportunities to build in resilience to climate impacts from the outset. It is also highlighted that the changing risks outlined in this report may affect the design of the Net Zero economy as it is important to plan the Net Zero transition so that it operates effectively and efficiently in the future climate, not the climate experienced in the recent past. In the context of this risk assessment, it is too early to provide an evidence-based analysis of how the risk profile will change. Instead implications of Net Zero are provided, where relevant, to provide an indication of whether the policy increases or decreases the risk and also whether climate change will make Net Zero harder or easier to achieve.

#### 4.1.2 The challenges of assessing climate risks to infrastructure

The transport, energy, ICT and water sectors are all fundamental to day-to-day life, yet *all* regularly face weather-related challenges. The nature of the future risk remains similar to previous risk assessments, but the latest climate change scenarios (UKCP18) do indicate significant differences in climate extremes that need to be taken into account. These are summarised in Chapter 1 (Slingo, 2021) and underpin the evidence in this chapter wherever possible. It also highlights the need to increasingly consider low likelihood, high impact events for the infrastructure network (see Box 4.3)

##### **Box 4.3: Low Likelihood, High Impact scenarios and Infrastructure**

Chapter 1 (Slingo, 2021) has illustrated how there is now increasing evidence towards significant changes in future extremes of temperature and rainfall, as well as a changing evidence base in Earth system instabilities. Such changes could result in ‘tipping points’ being passed, leading to high impact outcomes across the risk indicators covered in this chapter. If scenarios or events which are unlikely but more extreme do occur, they would then be more likely to trigger cascade impacts (I1) via interacting risks (see Box 4.4).

The evidence base for such outcomes remains limited, although some examples have been explored. For example, Yesudian and Dawson (2021) assessed the risk to airports worldwide from scenarios of sea level rise from Jevrajeva *et al.* (2018), which are higher than those in UKCP18.

These scenarios considered much larger contributions of ice loss from Antarctica than in the UKCP18 projections (De Conto and Pollard, 2016), which other work suggests may overestimate sea level rise risks this century (Edwards *et al.*, 2019). 1,238 airports were defined as being in the Low Elevation Coastal Zone (the area along the coast that is less than 10 m above sea level). Globally, the risk of disruption was projected to increase by a factor of 17–69 by 2100, depending on the rate of mean sea-level rise. A projected global mean sea level rise of 0.62 m by 2100 would place 100 airports around the world below mean sea level. While such a rise is almost the median projection for 2°C global warming by 2100 in that study, in UKCP18 it is at the upper end of the projected range for 2°C global warming by 2100 and the median for 4°C global warming by 2100 (see Chapter 1: Slingo, 2021). Yesudian and Dawson (2021) highlight that airports already benefit

from substantial flood protection that reduces present risk by a factor of 23 and to maintain risk in 2100 at current levels could cost up to \$57bn. Within the UK, London City airport ranked in the global top 20 by risk in 2100 for a 1.8 m global mean sea-level rise by 2100, which is the 95<sup>th</sup> percentile in the RCP8.5 scenarios considered by Yesudian and Dawson (2021) but substantially above the RCP8.5 95<sup>th</sup> percentile in UKCP18 (Palmer *et al.*, 2018).

Some changes, such as shifts in the Atlantic jet stream which underpins the UK's weather and storminess in general, can be sudden and cause unprecedented impacts. This was seen in 2020 when compound failures from two extreme storms in quick succession (Storms Ciara and Dennis) caused severe flood damage, with the impacts of the second storm felt even greater as it hindered clean-up operations from the first.

Weather and climate both impact on infrastructure performance and manifest in a variety of ways, but often lead to costly disruption or, in more severe cases, loss of service entirely. This has significant implications, not just for economic activity, but societal equity, health, and well-being more generally. However, there exists a continual trade-off between the cost of risk management versus the level of residual risk. Following NIC (2020), work is only just beginning on producing clear guidelines detailing the acceptability of loss of performance by the public, and indeed the willingness of the public to accept reduced levels of service when faced with an increasingly challenging operational environment (e.g. a climate emergency) in order to base such decisions. However, some sectors have begun this process. For example, as a starting point, water utility companies have surveyed the public to ascertain willingness to pay for investment in long-term adaptation measures.

A key consideration, particularly in light of the proposed investments, is the lifespan of infrastructure assets. Infrastructure is (mostly) designed for longevity and means that much of the infrastructure in existence today will be in place for the remainder of the century. Hence, there is a need to consider implications both for existing (potentially retrofitted) and new infrastructure. Climate change is actively considered when planning major new energy, transport, waste water and water projects under guidance from the UK Government's National Policy Statements, however guidance under the National Planning Policy Framework and Planning Guidance for smaller projects only considers flood risks and does not ensure other climate risks are considered (CCC, 2019b). For existing assets, adapting to climate change presents operators and owners with a challenge of coalescing and reconciling (where possible) actions across a range of aging assets, with differing design codes, environmental exposure, usage and maintenance regimes – all of which combine to determine how an asset may respond to a changing climate. Work is ongoing to introduce standards across Europe (see ISO 14090/14091) where the UK is represented by members of the Infrastructure Operators Adaptation Forum, but there is a sense that the inclusion of climate adaptation remains in its infancy. The CEN/CENELEC Coordination Group on Climate Change Adaptation (ACC-CG) has, as part of an EC mandate started in 2014, been steering the revision of 13 European standards to include adaptation to climate change. Translation of ISO 14090 into British Standards is also underway with a roadmap to be produced in due course. The British Standards Institution is currently developing BS 8631, due for publication by mid-2021, that provides guidance on developing and applying adaptation pathways to climate change adaptation planning and decision-making. However, it is highlighted that even when there is some guidance, designing climate-smart infrastructure in practice is extremely challenging. This is partly because of the high uncertainty around the future

climate (see Chapter 1: Slingo, 2021), and also because of the need to trade-off up-front costs versus long-term adaptation benefits (Watkiss *et al.*, 2019). For this reason, there has been a focus in the literature on decision making under uncertainty.

Additional complexity is added by the need to take a systems view (i.e. everything is interrelated and interdependent). No infrastructure network operates in isolation and a failure in one system can interact with others, and rapidly cascade into other sectors. Thus, system resilience to climate change goes beyond just the individual infrastructure networks. Indeed, interactions are not just limited to the infrastructure sector and can have far reaching consequences. As part of the 3<sup>rd</sup> Climate Change Risk Assessment, a project on Interacting Risks was commissioned to investigate this element (see Box 4.4).

### 4.1.3 Adaptation: Policy Considerations

The periodic CCRA is a requirement of the Climate Change Act 2008 and 2009 Climate Change (Scotland) Act. An additional key requirement in the Act was the production of climate change adaptation reports which can be requested by the Secretary of State. This process, known as *Adaptation Reporting Power* (ARP) in England, has been widely adopted across the infrastructure sector with a total of 91 assessments received during the first round of reporting. Although the process became voluntary in subsequent rounds, infrastructure related organisations / operators represent the vast majority of respondents (75/88) who have volunteered to report in the latest (third) round due in 2021. Although this is an excellent response rate, it is problematic for CCRA in two ways. Firstly, not all critical organisations are reporting and as such recommendations have since been made by the Climate Change Committee to reinstate compulsory reporting to ensure evidence is captured which is unable to be acquired easily by other ways. Secondly, the submission date for the third round of ARP is beyond the evidence capture phase of this CCRA and therefore is unavailable for inclusion and scrutiny. As such, there is a reliance on the second round of reporting, which demonstrated that whilst good consideration is being achieved in assessing risks and appropriate adaptation responses were underway, the reporting was too vague to provide any detailed assessment of progress (CCC, 2019b). Thus, steps 2 and 3 of the CCRA3 methodology which are focussed on adaptation consider reported progress on adaptation from the Climate Change Committee (Progress Reports), as well as input on policy developments from a range of industry representatives.

Policy continues to evolve in the infrastructure space, following on from the National Policy Statement (England & Wales) published in 2014, the Climate Change Adaptation Programme (Scotland) and the Northern Ireland Climate Change Adaptation plan. These have led to sector-level policy responses in the form of Sector Security & Resilience Plans (SSRPs), coordinated by the Cabinet Office Civil Contingencies Secretariat. Resilience of assets to relevant risks is detailed in the SSRPs, but as reported in CCRA2, there is no clear link between them and adaptation planning. Recent development in this area has been highlighted by the NIC (2020) which promotes a statutory requirement for regulators in the infrastructure sector to have resilience duties.

## 4.2. Risks to infrastructure networks (water, energy, transport, ICT) from cascading failures (I1)

Infrastructure operates as a system of systems. It means that vulnerabilities on one network can cause problems on others, and therefore be far reaching beyond the infrastructure sector. Given the wide-ranging nature of the linkages, a full understanding of the impacts of cascading failures is difficult to ascertain. However, the vulnerability of interconnected systems may be significantly underestimated (Mao and Li, 2018). This is increasingly evidenced, albeit anecdotally, by high-profile case studies, but the limitation of this approach means that it is difficult to understand, with confidence, the full magnitude of future risks in this area.

Case studies (such as the August 2019 power cuts) and literature support an assessment of current risk being high magnitude, with high confidence, with disruption in urban areas potentially impacting hundreds of thousands of people annually. Future magnitude is given as high with medium confidence for all four nations.

Whilst there are many examples of best practice adaptation within individual infrastructure sectors, the practice of focusing efforts in this way means opportunities are being missed to improve resilience across the sector more generally. The lack of a systematic national assessment of interdependency risk, the poor assessment of progress on adaptation in this area, and the low likelihood that sufficient non-governmental action will be undertaken indicates that this risk is not currently being managed, and that only partial plans are in place to do so. Because of the high projected magnitude for this risk and the view that current and announced adaptation will not fully manage the risk, it has been scored as more action needed across the whole of the UK.

### 4.2.1 Current and future level of risk (I1)

#### 4.2.1.1 Current risk (I1)

Note: it has not been possible to split the evidence by UK country for this risk.

##### 4.2.1.1.1 Current risk - UK-wide (I1)

Infrastructure networks do not operate in isolation. They can be interdependent because (i) their services are reliant on other networks for power, fuel supplies and ICT; or (ii) they are co-located and experience the same hazard; or (iii) they are managed or used by the same organisations or people (Dawson, 2015). As such, failures can cascade from one infrastructure network to another, often caused by multi-hazards, cascade hazards and compound hazards (AghaKouchak *et al.*, 2018).

Infrastructure systems featured heavily in CCRA3 research on Interacting Risks (WSP, 2020) (see Box 4.4), which provides an understanding of how risks can cascade across, and interact beyond, the infrastructure sector. Indeed, the majority of risks studied described interactions within the infrastructure sector, such as coastal flooding causing power infrastructure inundation, or power

supply interruption leading to impacts on travel and freight operations. However, there are also clear links to other sectors, such as water supply interruptions leading to health and welfare impacts (see Chapter 5, Health, Communities and the Built Environment: Kovats and Brisley, 2021). Overall, WSP (2020) identified 7 interactions with a high impact magnitude score for the baseline period, with 13 scored as medium and 7 as low impact. System interdependencies are mapped in the National Infrastructure Commission's Resilience Study, which details how national-level decisions (such as policies, incentives, markets and other factors) influence UK infrastructure Levels of Service (ARUP, 2020).

CCRA2 (Dawson *et al.*, 2016) specifically reported on interruptions to the supply of biomass to power stations following flooding of the Port of Immingham in December 2013. Critical power and IT services were lost, causing the cessation of operations for a number of days. In the same month, flooding of the M23 motorway and railway station hampered the ability of staff to travel to Gatwick airport. Flooding of substations during the event at Gatwick resulted in disruption to 13,000 airline travellers (McMillan, 2014). In addition to these previously reported examples, a further notable event was the loss of electrical power at a major exchange in Birmingham in 2011 which led to the loss of broadband connection to hundreds of thousands of customers in the UK (BBC, 2011).

More recently, power outages in England and Wales on the 9<sup>th</sup> of August 2019 demonstrate the potential for cascading infrastructure failure (Ofgem, 2020a). The event was triggered by a lightning strike on the Eaton Socon-Wymondley circuit between Cambridgeshire and Hertfordshire, causing a routine fault on the national electricity transmission system and the disconnection of a number of small generators connected to the local distribution network. Simultaneously, two larger generators (Hornsea 1 Limited and Little Barford) experienced technical issues and were unable to provide power. The combined power losses exceeded the back-up power generation capacity of the Electricity System Operator (ESO), triggering a power outage. A total of 892 megawatts (MW) of net demand was disconnected from local distribution networks. The electricity supply of over 1 million consumers was interrupted. The outage had significant knock-on impacts for the rail sector, with the Train Operating Company (TOC) Govia Thameslink Railway experiencing stranded trains, triggered by on-board automatic safety systems. This in turn caused knock-on delays across the rail network (Ofgem, 2020a). Hornsea 1 Limited and RWE Generation UK plc (operators of Little Barford) each agreed to make voluntary payments of £4.5m to the Energy Industry Voluntary Redress Scheme.

Storms, heavy rainfall and flooding are often precursors to cascade events (e.g. Storm Desmond (see above) and Hurricane Katrina, (Leavitt and Kiefer, 2006)). Indeed, the Environment Agency's long-term investment scenarios show that over 40% of transport and utilities infrastructure are in areas at current risk of flooding, either directly or due to dependence on other sectors (Environment Agency, 2019a). Further examples of the current magnitude of the impact of cascading failures include the flooding of a substation in Lancaster following rainfall associated with Storm Desmond in December 2015, leaving the city without power for more than 30 hours. This had consequences for transportation (no traffic lights, no lighting at the train station, refuelling issues), telecommunications (no mobile network, internet or digital radio), and water supply in some areas (Kemp, 2016; Ferranti *et al.*, 2017). In this example, the failure was caused by a combination of hazards; (i) eight weeks of wet weather had left the Lune catchment saturated, and water levels high, the two-day rainfall was (at the time) a rainfall record for Lancaster; and (ii) an incoming high

tide (Ferranti *et al.*, 2017). Although an extreme case, winters in the most recent decade in the UK (2009-2018) are now 12% wetter than 1961-1990, with the total rainfall from heavy rainfall events increasing by 17% (2008-2017) (Met Office, 2019a).

Since CCRA2, there have been several new academic approaches to studying interdependencies. For example, Pescaroli and Alexander (2018) have developed a framework to describe risk, classifying it as: compound, interconnected, interacting, and cascading. In addition, Murdock *et al.* (2018) presents a method for quantifying disruption caused by different failures to visualise information using interdependency circle diagrams. Crucially, recent international research has indicated that the vulnerability of interconnected systems may be underestimated. Mao and Li (2018) modelled the resilience lifecycle of an electric power system, a telecommunication system, and a water supply system and noted that excluding interdependencies gave a misleading impression of total resilience.

Much of the recent UK-based research on cascading risks from infrastructure interdependencies is focused on the potential impact of flooding hazards. Many of these studies use a simulation approach, for instance, Thacker *et al.* (2017a) simulate the interdependencies between the electricity network and the domestic flight network, demonstrating the potential for large disruptions resulting from the failure of electricity assets. Ranking the top 500 electricity transmission and sub-transmission assets in the UK, the simulation indicates that the most critical assets are capable of disrupting over 4 million customers. A similar picture is seen for potential disruptions to airport customers, with an increasing criticality at the higher tiers of the transmission hierarchy, but with individual assets at all levels capable of similarly high impacts (i.e. each impacting in excess of 190,000 customers). It must be noted that this is a simulation and has not been validated against real data. It is not clear whether the level of redundancy (i.e. the ability to manage disruptions through the network) during outages of key assets is reflective of the situation during observed events.

Thacker *et al.* (2017b) studied the spatial distribution of risk from cascading failures between infrastructure systems. By testing 200,000 failure scenarios, the study identifies that hotspots tend to be located at the periphery of urban areas where high concentrations of users will be impacted (hence demand) and critical infrastructures are concentrated.

Thacker *et al.* (2018) utilised an approach where data on critical infrastructure asset networks (including electricity generation, transmission and distribution, airports, water towers, wastewater treatment and telecom masts) are given synthetic connections based on distance and intersected with probabilistic hazard maps (in this case the National Flood Risk Assessment (NaFRA) flood likelihood map data) to calculate expected annual damages from flooding of electricity substations. Although simulated, the results show the potential for large-scale knock-on costs. The largest indirect sector impacts correspond to the business services and real estate sectors as well as the mining sector.

Pant *et al.* (2020) modelled a failure event initiated in the electricity network. The study estimated direct economic losses and total economic losses using an Input-Output (IO) model by assuming service disruptions lasted for 24 hours (with economic losses corresponding to losing demand from the equivalent of 24 hours of customers across sectors). Due to the forward and backward linkages

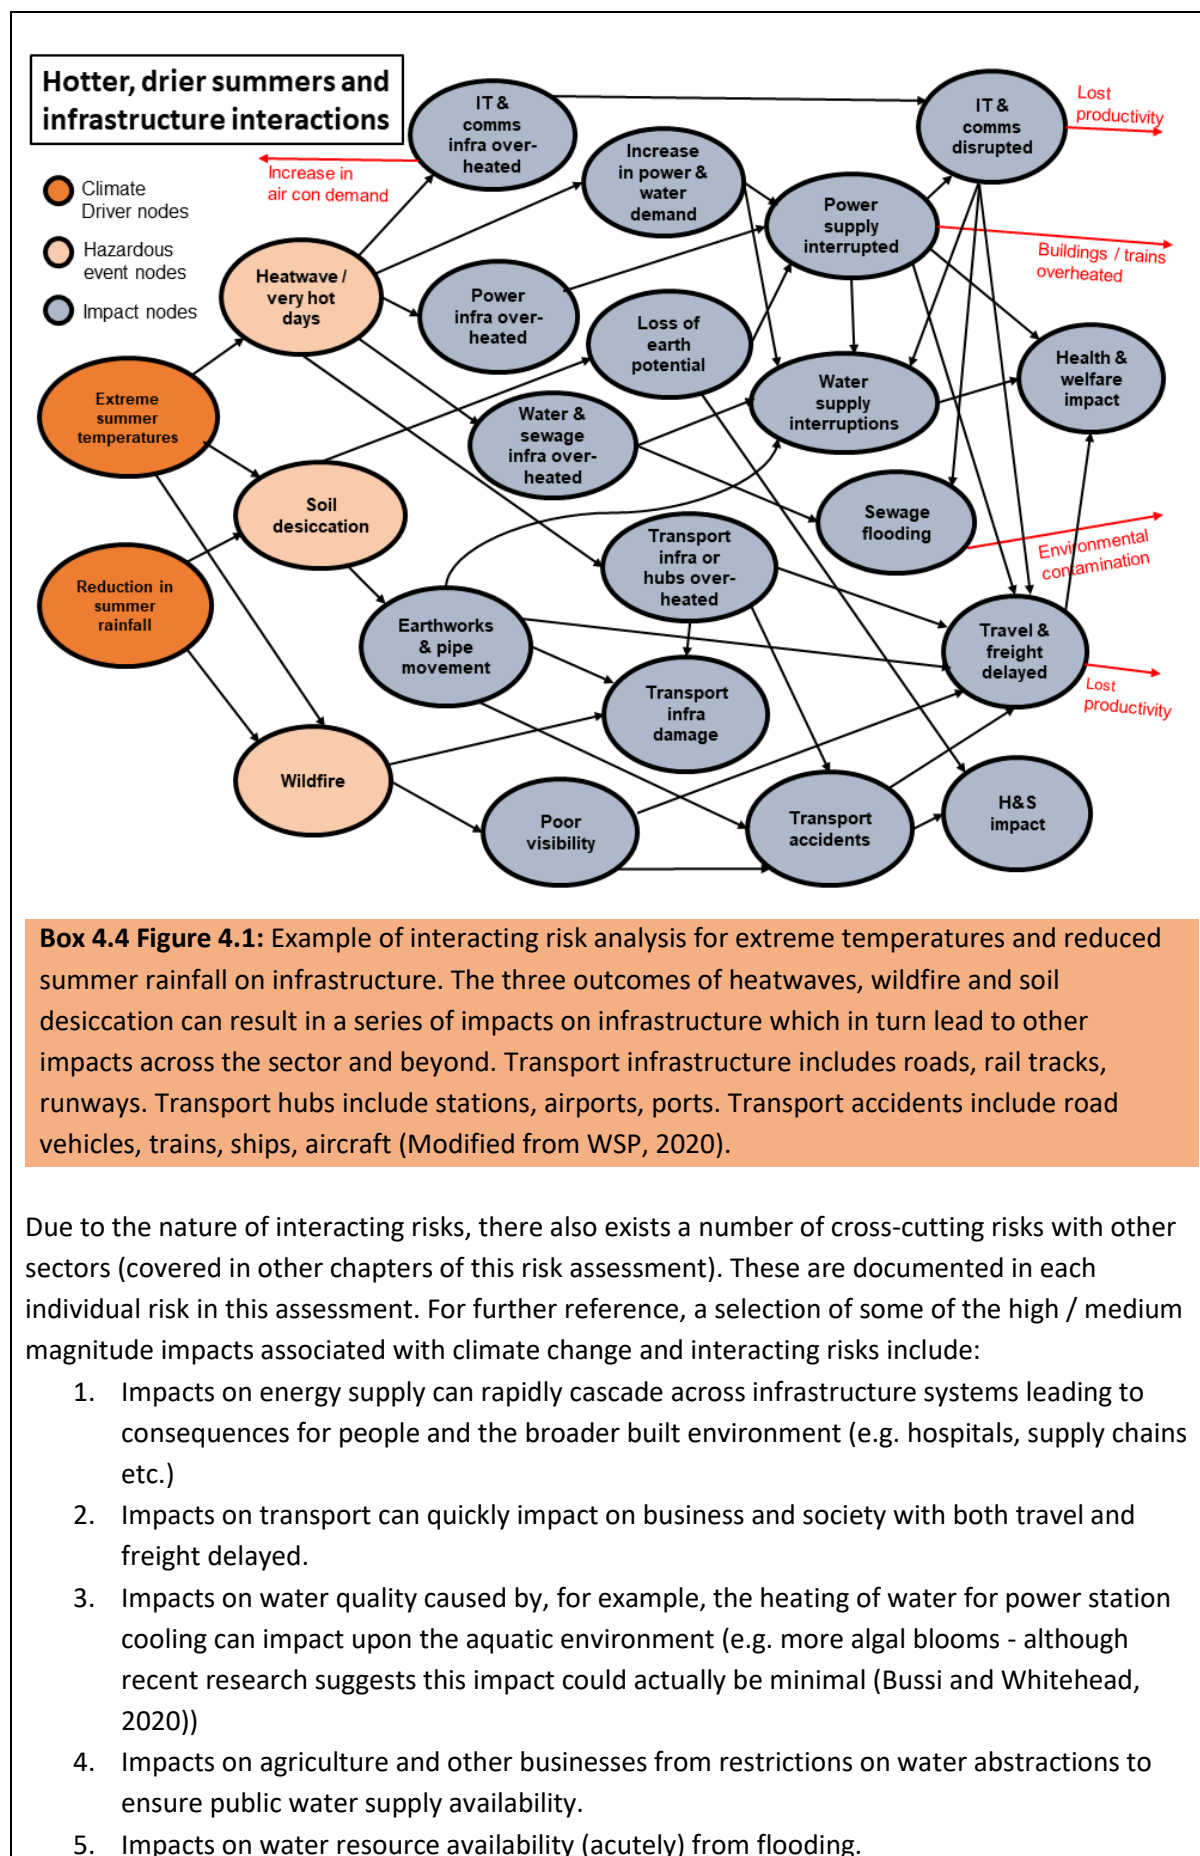

in the economic IO model, there are indirect economic losses to all sectors that use electricity, telecoms and railways outputs, and some of these losses feedback to these infrastructure sectors as well (Pant *et al.*, 2020).

Koks *et al.* (2019) used geospatial information on the location of electricity infrastructure assets and local industrial areas and employed a multiregional supply-use model of the UK economy to trace the impacts of floods of different return intervals across 37 subnational regions of the UK. The authors used the loss in labour productivity (temporary reduced employment) as the proxy for business disruption. The results show up to a 300% increase in total economic losses when power outages are included in the risk assessment, compared to analysis that just includes the economic impacts of business interruption due to flooded business premises (Koks *et al.*, 2019). The authors estimated that the total economic loss resulting from failure of five substations (worst case scenario) to be around £27 million per day.

#### **Box 4.4 Interacting risks and Infrastructure**

Interacting risks pose one of the biggest challenges when assessing climate risks more generally. Disruption on one infrastructure network can quickly cascade onto other infrastructure networks, but it is also important to recognise that infrastructure is a key enabler of the UK economy and underpins many key activities. The CCRA3 Interacting Risks project (WSP, 2020) demonstrated that the consequences of impacts due to climate changes on individual parts of the infrastructure network have far wider repercussions for the natural and built environment. Considering these wider effects, the magnitude of the impact far exceeds the effects on the infrastructure itself. There are numerous examples of this phenomenon. Interruption to power supplies is frequently highlighted as a key example of a source of cascade failure, but there are many others. For example, flooding (or other significant disruption) of transport networks can prevent key workers from operating other pieces of critical infrastructure. Fundamentally, access routes to key assets (e.g. nuclear power plants) may not be protected to the same level as the asset itself. Reliance on IT and communications infrastructure as an example of a current and increasing risk. Modelling of knock-on (downstream) nodes from a particular risk enables a qualitative assessment of further impact. Indeed, the interruption of power supplies is the single risk with the highest impact across the entire risk assessment and would be a root cause of large-scale impact across the sector. Disruption of IT and communication services is the second highest impact risk with significant downstream impacts. Other impacts were shown to be affected by a high number of risks further up a chain of interactions. The project found that risks emanating from other sectors caused delays to travel and freight more so than other impacts. As an example, Box 4.4 Figure 4.1 illustrates how these two risks can manifest as a direct result of extreme heat and a reduction in summer rainfall.

6. Impacts from displaced risks caused by flood management schemes (both coastal and fluvial)
7. Impacts on the marine environment from increased coastal erosion exposing old landfill sites.

Policy makers can use this information to better target adaptation efforts to improve the resilience against key risks which have the potential to cause the most upstream and downstream interacting impacts (e.g. multi-party agreements to allow the management of resilience risks by exploiting differences between sectors / locations). This has implications for the urgency in which measures are implemented.

#### 4.2.1.2. Future risk (I1)

Note: it has not been possible to split the evidence by UK country for this risk.

##### 4.2.1.2.1. Future risk – UK-wide (I1)

WSP (2020) projected the change in impact magnitude of infrastructure interactions for scenarios of global warming reaching approximately 2°C and 4°C in the late 21<sup>st</sup> Century (2070-2099) with large uncertainty<sup>1</sup>, scaled with macroeconomic growth (GDP and population growth projections) to account for future impacts being larger than today. This utilised the network maps showing principal interactions within and between the sectors (Box 4.4) with impacts being simulated based on knowledge of interactions between weather and the components in question. Projections for both the 2050s and the 2080s suggest that significant interactions in the infrastructure sector are more likely to occur and/or have greater impacts in the future, therefore with the current risk magnitude already high, the future risk magnitude can also be judged as high across the UK in scenarios of both 2°C and 4°C global warming at the end of the century (Table 4.2).

Impact ratings in the CCRA3 Interacting Risks magnitude framework are defined as follows for impacts on infrastructure:

**High** – Major annual damage and disruption or foregone opportunities (£hundreds of millions and/or hundreds of thousands of people affected)

**Medium** - Moderate annual damage and disruption or foregone opportunities (£tens of millions and/or tens of thousands of people affected)

**Low** - Minor annual damage and disruption or foregone opportunities (less than £10 million and/or thousands of people affected).

<sup>1</sup> UKCP18 probabilistic projections with RCP2.6 and RCP8.5 emissions, with 5<sup>th</sup>, 50<sup>th</sup> and 95<sup>th</sup> percentiles respectively reaching global warming of 1.1°C, 1.9°C and 2.8 °C (RCP2.6) and 3.0°C, 4.2°C and 5.8°C (RCP8.5) in 2070-2099. The RCP2.6 range approximately matches the lower CCRA3 scenario, and the RCP8.5 range includes the CCRA3 higher scenario but extends both slightly below and considerably above this (see Chapter 2: Watkiss and Betts, 2021).

**Table 4.2** Summary of the most significant risk pathways modelled in the CCRA3 Interacting Risks project (WSP, 2020), along with the impact ratings (based on annual average impact and likelihood) in 2020 and 2080.

Climate drivers	Hazardous events	Main impact cascades		2020	2080
Increase in summer temperatures and reduction in summer mean rainfall	Heatwaves and very hot days	Transport infrastructure overheating, or disruption to IT and communications services	Travel and freight delays	Low	Medium
			Transport infrastructure damage	Medium	Medium
Extreme winter rainfall events and increase in winter mean rainfall	River, surface and groundwater flooding	Power infrastructure flooded	Power supply disrupted	Low	Low
		Water, sewerage infrastructure flooded, reduced water quality or power supply disrupted	Water supply disrupted	Low	Medium
			Sewer flooding	Low	Medium
		Transport hubs or infrastructure flooded, or power supply disrupted	Travel and freight delays	Medium	High
		Damaging water flows, slope or embankment failure	Transport infrastructure damage	Medium	High

The most significant interactions are those which result in travel and freight delay or damage to transport infrastructure. The most significant cross-sectoral interaction highlighted was linked to natural environment interactions (e.g. flooding leading to reduced water quality in the natural environment leading to water supply disruptions). However, drought leading to low reservoir levels and water supply disruptions was also found to be significant in the 2050s and 2080s in the higher warming scenario by 2100 (changes in drought frequency are uncertain and were modelled on a

‘what-if’ basis in the project).

#### 4.2.1.3. Lock-in and thresholds (I1)

As highlighted in Box 2, the major cause of lock-in for this risk stems from high levels of infrastructure development planned for the near future (as per the National Infrastructure Plan). Infrastructure has a long lifetime and thus has an increased likelihood of facing future climate risks, while it could also be difficult or costly to retrofit adaptation later. In more specific terms, there is a concentration of lock-in risks because of an increasing reliance on electricity and ICT with all infrastructure sectors requiring power for some (if not all) of their assets. This situation is particularly acute in the transport sector due to the increasing electrification of transport systems and vehicles. The increasing dependence in utilities of telemetry/remote inspection means that the vulnerability to ICT failure is increasing very rapidly. Developments such as the likely introduction of autonomous transport technologies over the next 30-50 years will introduce new interdependencies and change the nature of cascading failure risks in the infrastructure system. Uptake of concepts such as digital twins, and the real-time management of assets management, will further increase reliance on power systems. CCRA2 noted there is insufficient information about the location of ICT and the criticality of its function. There are some modelling approaches that incorporate ICT systems, but these are not UK based.

Thresholds for cascade failure are difficult to define. When dealing with a system of systems, the network is effectively as strong as the weakest link. Although thresholds will exist for individual risks on individual assets, defining a clear threshold where a cascade failure will occur is an imprecise science given the range of compound hazards and interactions needing to be considered. This remains an important area for future research.

#### 4.2.1.4. Cross-cutting risks and inter-dependencies (I1)

Owing to its nature, this risk has interactions with many other risks within the infrastructure sector and beyond. As well as the information on interdependencies, WSP (2020) identified the impacts which have the greatest number of downstream connections (i.e. have the greatest potential for cascading failures throughout the infrastructure system and wider economy). In terms of infrastructure, power supply interruption has the highest number of connections (15, with 11 being in the infrastructure sector and 4 in the built environment), followed by IT and communications disruption (10, with 7 in the infrastructure sector and 3 in the built environment) and transport infrastructure/hub flooding (7, with 4 in the infrastructure sector and 3 in the built environment). Looking at impacts with large numbers of upstream connections (which can be affected from a number of different sources), those that are affected most by the infrastructure sector are travel and freight delays (13 connections with the infrastructure sector), water supply interruptions (9 connections), transport accidents, power supply interruptions, transport infrastructure damage and sewage flooding (all with 5 connections).

#### 4.2.1.5 Implications of Net Zero (I1)

At present, no studies have assessed the extent to which future socio-economic scenarios or

planned developments to achieve Net Zero in the UK will affect the exposure and vulnerability of infrastructure systems to climate hazards. However, power supply interruption, and transport infrastructure/hub flooding are both identified in the literature as highly connected impacts with high potential for cascading failures. Both of these systems feature heavily in the CCC Net Zero Technical Report (CCC, 2019b) and the CCC's 2020 advice on the Sixth Carbon Budget (CCC, 2020a) as key areas for meeting emissions targets, hence future exposure and vulnerability will potentially be influenced by forthcoming recommendations / policy in this area. It is therefore possible that the Net Zero target could concentrate system risks. As an example, electrification of cars (as well as household energy supply, see risk H6) will increase the potential impact of power shortages brought on by weather related events. The increase in future climate change and the growing level of potential interacting and cascading risks could make the Net Zero target more difficult to achieve, in that it is likely to involve additional costs (for climate smart design) and might require greater margins for management in the system.

#### 4.2.1.6 Inequalities (I1)

At present, no studies exist which specifically assess the observed inequality of risks to individuals/groups. The spatial hotspot analysis by Thacker *et al.* (2017a) demonstrates the importance of large urban areas of England and Wales for both demand for infrastructure services and their ability to accommodate these (especially in the periphery of urban areas). This analysis is based on simulation and also identifies important transport corridors between settlements. The CCRA3 interacting risks project (WSP, 2020) shows that of the 98 interactions (defined as a pair of connected hazardous event or impact nodes, excluding the climate driver nodes) taken into consideration in the infrastructure sector, 6 (2%) were defined as having coastal impacts only. For the remaining 92 interactions, the impacts are likely to be felt in multiple locations (i.e. both urban and rural areas, and the coastal zone). The study concludes that for the vast majority of interactions it is not possible to state that they are more important at one location over another. The consequences of this risk are high across England, Wales, Scotland and Northern Ireland.

#### 4.2.1.7 Magnitude scores (I1)

The case studies and literature support an assessment of current high magnitude of risk with high confidence, with disruption in urban areas potentially impacting hundreds of thousands of people annually. WSP (2020) supports a continuation of high magnitude risk in the future, given that the size of the impact from cascading effects increases over time.

Although the existing literature on the potential impact of climate change on cascading failures in the infrastructure sector is limited, the evidence for future risk to the individual components of the infrastructure system contained in this chapter (for example, risks to energy, risks to infrastructure from river, surface, groundwater and coastal flooding) supports a medium level of confidence for a continued high magnitude risk of cascading infrastructure failure for all nations of the UK for the 2050s and 2080s under pathways to 2°C and 4°C global warming at the end of the 21<sup>st</sup> Century.

**Table 4.3 Magnitude scores for risks to infrastructure networks (water, energy, transport, ICT) from cascading failures**

Country	Present Day	2050s		2080s	
		On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century	On a pathway to stabilising global warming at 2°C by 2100	On a pathway to 4°C global warming at end of century
<b>England</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)
<b>Northern Ireland</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)
<b>Scotland</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)
<b>Wales</b>	High  (High confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)	High  (Medium confidence)

#### 4.2.2 Extent to which current adaptation will manage the risk (I1)

##### 4.2.2.1. Effects of current adaptation policy and commitments on current and future risks (I1)

###### 4.2.2.1.1. UK-wide

The CCC (2019b) state there is no systematic national assessment of interdependency risk or a framework to improve resilience at the UK level, including addressing risks and opportunities from climate change. The general approach to manage cascade failure is by tackling individual risks on individual infrastructure networks. As a result, although the risks to individual components or systems are reduced, opportunities and efficiencies that could be gained by taking a whole-systems approach are often missed. As this work to build resilience is ongoing (at various levels), then the risk will be reduced somewhat by current adaptation efforts across specific sectors. The cumulative impact of these efforts on general cascade failures is unknown and as such expert judgement is required on the extent to which those efforts will manage the risk (as demonstrated in the CCRA3 Interacting Risks project).

A better understanding of cascade failures and improved efforts for data sharing could significantly reduce any adaptation shortfall. The OECD highlights the importance of specialist networking groups
